The results of these models (borne out by observation) demonstrate the dangers of vaccinating at coverages well below that required for elimination. Although those individuals vaccinated are protected, those who are not vaccinated experience an increased average age at infection and hence a greater risk of disease. The population level benefit derived from the vaccinated does not necessarily outweigh the worsened situation in the unvaccinated. This situation is complicated when vaccine is available through private purchase, because the distribution of benefit and detriment might be expected to exacerbate inequalities (Vynnycky et al. 2003).

To prevent recurrent epidemics in a vaccinated population, it has become increasingly common to recommend multiple schedules, i.e. vaccine is offered twice at different ages (Babad et al. 1995). The two-dose MMR vaccine program in the UK was supported by modeling, as was the MR 'catch-up' campaign (Gay et al. 1995).

Design of vaccination programmes: hepatitis B virus

The disease caused by HBV infection can be divided into acute and chronic. Acute disease occurs during the weeks and months after infection, and, like many other viral infections (e.g. rubella), the risk of disease probably increases with age at infection. If the immune response is able to clear the infection, the individual is

left solidly immune to further infection. The alternative outcome is that a chronic infection develops and individuals become infectious carriers, and can remain so for many years. The risk of developing chronic carriage is highly age dependent: over 90 percent for infected infants and perhaps 5 percent for adults. The sequelae of chronic carriage include cirrhosis and primary hepatic cancer. There are safe, cheap, and effective vaccines to prevent acute infection. How should they be used?

The answer to this question will depend on the epidemiology of the infection, which varies dramatically across the globe. In The Gambia (west Africa) HBV is a childhood infection, with over 80 percent of children infected by the age of 10 years. The exact route of transmission is essentially unknown. As the risk of developing carriage is higher for those infected as children, the proportion of the population with chronic infection in areas of high endemicity is also high (perhaps as high as 10 percent). In complete contrast, in countries such as the UK, HBV is essentially an adult infection, with the majority of transmission associated with sexual contact or intravenous drug use. Consequently, carriage is relatively rare, and certainly less than 1 percent in the general population (Hahne et al. 2004). Between these two extremes, there is a whole range of endemicities (e.g. Coursaget et al. 1994).

There is little doubt that immunization is indicated in areas of high endemicity (e.g. Edmunds et al. 1996), but in low endemic populations the risk of infection is so low that there is some debate as to whether mass immunization is required, and is essentially a cost-effectiveness issue (see below). However, the relationship between average age at infection and probability of developing carriage provides a possible explanation for the global variation in HBV endemicity (Medley et al. 2001). If this process is important, the effect of vaccination is further enhanced.

Cost-effectiveness and health economics

Decisions concerning the implementation of any public health intervention should involve a consideration of the economic costs and expected health gains. Models of the type discussed here are capable of providing predictions of the latter, but care needs to be taken to ensure that the two frameworks are compatible in terms of scope (or perspective) and discounting. In particular, the prediction of the health impact of introducing a vaccine should include consideration of the effect on unprotected individuals (Edmunds et al. 1999).

Quantitative prediction

As mathematical models deal with numbers, for most non-modelers it would seem that the principal use of models should be to provide quantitative predictions. However, we hope that this chapter has demonstrated that accurate quantitative prediction is very difficult, and that qualitative prediction and increased understanding are the best output. Even in situations where the only value of the model is numerical prediction (e.g. Ghani et al. 2003), the predictions provide a test of our understanding; if the predictions are wrong, clearly there are processes that are not included or fully understood – the model is wrong. Note, however, that, if predictions prove correct, this is not proof of model correctness. In situations where models are intended to guide policy, testing them against data through prediction does provide some validation. When models are not validated against data, they have no such empirical support.

Evolution

Another unique feature of infectious disease (in contrast to noninfectious) is that the organisms involved (hosts and pathogens) are subject to evolutionary change. As pathogens usually have a much shorter generation time than their hosts, they are expected to evolve faster. In terms of vaccination, a pathogen strain that is able to circumvent the immunity provided by a vaccine has a large population of 'susceptibles' to infect. However, McLean (1995) argues persuasively that, even if such an escape mutant occurs, it will be less infectious and therefore easier to control than the original pathogen. Until such an event arises and is well documented, these predictions remain untested.

CONCLUSIONS

Given a reasonable understanding of the natural history of an infection within the typical individual and the key factors leading to transmission between individuals, mathematical models may be developed that capture the essence of infection dynamics within a population of hosts. Such models can be put to various uses in relation to vaccine intervention, ranging from developing our understanding of underlying principles to detailed cost-effectiveness analyses.

To date, most modeling work has been undertaken retrospectively to understand why things have or have not happened as a result of vaccine intervention. However, the understanding that arises from using quantitative methods to study the transmission dynamics of infectious disease is becoming widespread. Fine (1994) suggests that it is as much the conceptual issues that modeling has developed which has been instructive to those on the policy-making committees, rather than a targeted modeling study that has led the specific decision being made.

Our own perspective, of course, is that modeling should be a requirement for the assessment of any public health intervention, including vaccination. But that this modeling

should take its place as a source of information and a vehicle for testing knowledge and understanding, rather than as a definitive prediction of outcome. To return to our bridge analogy – building a bridge without predicting its effect on traffic flow or probability of collapse is irresponsible, so why implement a vaccination program without calculating its expected effects?

Since the beginnings of medical mycology at the turn of the century, with the discovery of the principal agents of human and animal mycoses (ringworm, aspergillosis, candidosis, cryptococcosis, histoplasmosis, etc.), there has been continual progress in our knowledge of pathogenic fungi that cause diseases and their role in the pathology of infectious diseases.

The pathogenic fungi and the mycoses, which have emerged in recent years in the immunocompromised host, have emphasized the importance of medical mycology, within the discipline of medical microbiology. This has been made possible by the pioneers in medical mycology, and by enthusiastic medical mycologists who founded the International Society of Human and Animal Mycology (ISHAM) in 1954. This now has more than 1 000 members and a score of affiliated medical mycological societies throughout the world. The expansion, over the past 50 years, of the spectrum of fungal infections, the clinical and pathological aspects of the mycoses, the ecology and epidemiology of the classical pathogenic and opportunistic fungi, as defined in 1962 at the International Symposium on Opportunistic Infections, has been accompanied by an increased understanding of pathogenic fungi and the mycoses. The physiology, biochemistry, immunology, morphogenesis (studied by transmission and scanning electron microscopy), sexuality, genetics, and molecular biology of fungi pathogenic to humans and animals have been studied in depth.

Many of the systemic mycoses have been known since the end of the nineteenth century, but they were considered to be extremely rare, usually discovered postmortem, and observed only in compromised patients. In recent decades, since the introduction of antimicrobials in 1945, of corticosteroids in 1950, of immunosuppressive therapy

in 1960, of catheters, prosthetic devices, and organ transplantation in the 1960s and 1970s, and with the emergence of the acquired immunodeficiency syndrome (AIDS) and the increasing use of bone marrow grafting in the 1980s, these deep mycoses have started to develop new clinical aspects, occurring with high frequency and severity. Many of the opportunistic mycoses are now nosocomial, hospital-acquired, invasive infections caused by a new spectrum of opportunistic pathogenic fungi (Bodey 1988; Weber and Rutala 1988; Jarvis 1995).

FUNGI IN NATURE AND PATHOLOGY: CLASSIFICATION

Among the more than 72 000 described species of fungi that are widespread in nature (soil, plants, water, air), more than 300 are now recognized as true pathogens or potential pathogens responsible for mycoses in humans and animals. The word fungus is derived from the Latin *fungus*, which came into use in the fifteenth century. The Latin was derived from the Greek *sphongirs* or sponge. The term 'mycosis' was derived from the Greek word *mykes* for mushroom.

The Fungi represent one of the five kingdoms of organisms classified, according to Whittaker (1969) and Margulis and Schwartz (1988), into three levels of organization:

1. the prokaryotes (kingdom Monera, including bacteria, actinomycetes, blue–green bacteria)
2. the unicellular eukaryotes (kingdom Protoctista), protozoa, nucleated algae, oomycetes)
3. the eukaryotes (kingdom Fungi, Plantae or Animalia).

The actinomycetes, which are true bacteria, have traditionally been studied by medical mycologists because, like fungi, they have mycelial forms and cause similar diseases.

The boundaries of these kingdoms and their components are still not well delineated. In the past, the causative agents for key mycoses, such as histoplasmosis (*Histoplasma capsulatum* var. *capsulatum*), which was discovered in 1906 by Darling, and coccidioidomycosis (*Coccidioides immitis*), which has been known since 1892 (Posadas 1892; Wernicke 1892; Rixford and Gilchrist 1896), were described by protozoologists as 'protozoans' because of their invasive unicellular tissue forms. They were recognized as fungi many years later – *H. capsulatum* var. *capsulatum* in 1934 by DeMonbreun, and *C. immitis* in 1900 by Ophüls and Moffitt – when they were isolated and cultured in their mycelial, saprophytic form.

Even now, revolutionary changes may occur, as with *Pneumocystic carinii*, which was reclassified as a fungus by molecular taxonomists because of its ribosomal RNA (rRNA) sequences (Edman et al. 1988). The study of the 5S rRNA of *P. carinii* showed that its phylogenetic position is closely associated with the Rhizopoda (ameba), Myxomycota, and Zygomycota (Watanabe et al. 1989); the most recent genetic studies in biomolecular taxonomy reinforced the close relationship of this organism to fungi rather than protozoa (Cushion et al. 1994) (see also *Pneumocystis* pneumonia).

Two algae that lack chlorophyll and have long been included in the kingdom Protoctista are dealt with by medical mycologists. The first of these species was described as *Prototheca zopfii* by Krüger in 1894 and the second as *Prototheca wickerhamii* by Tubaki and Sonida in 1954; they have been recognized, since the first proven infection in humans found by Davies et al. in 1964, as new pathogens (Ravisse et al. 1993).

Oomycetes are also within the province of medical mycologists. *Pythium insidiosum* (de Cock et al. 1987) was first described by Bridges and Emmons (1961) as *Hyphomyces destruens* in infected horses; it is now an emerging agent of animal (cattle, dogs, and cats) and of human infections in Australia, Japan, Latin America, Thailand, and the USA (Mendoza et al. 1996).

The principal fungi causing the mycoses are responsible for:

- superficial and cutaneous mycoses
- deep, systemic mycoses caused by the opportunistic yeasts or filamentous fungi or highly pathogenic dimorphic fungi that are introduced primarily into the respiratory tract (Figures 1 and 2) and
- subcutaneous mycoses.

This clinical classification is not rigorous because superficial fungal infections may become systemic mycoses that present as mucocutaneous manifestations.

MILESTONES OF MEDICAL MYCOLOGY

In two fascinating books, one devoted to the history of mycology (Ainsworth 1976) and the other to the history of medical and veterinary mycology (Ainsworth 1986), Ainsworth, the author and former Director of the Commonwealth Mycological Institute (at Kew in the UK), gives a straightforward account of the main views held about fungi in the past three millennia and the development of the study of fungi as a branch of the science of medical microbiology over the last 250 years.

As emphasized by Ajello (1975a), the evolution of medical mycology can be compared to the great network of roads that linked the farthest reaches of the Roman empire to the Eternal City, where at designated distances between cities, stone pillars were erected to mark the miles. The milestones of medical mycology were designated by Ainsworth (Ainsworth 1976, 1986; Ainsworth and Stockdale 1984), Ajello (1975a), Emmons et al. (1977), Seeliger (1985, 1988), Rippon (1988), and numerous other authors in their introductions to books and articles (Baldwin 1981; Huntington 1985; Drouhet 1991; Kwon-Chung and Bennett 1992).

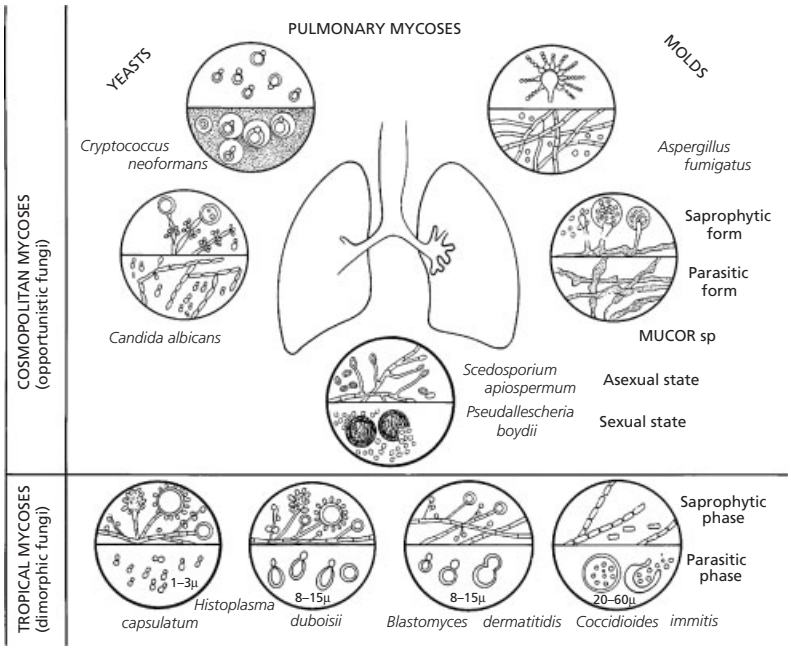

Figure 1 *Principal fungi responsible for pulmonary and deep mycoses: saprophytic form (upper hemisphere) and parasitic form (lower hemisphere). For* Scedosporium apiospermum *(asexual state), the sexual stage is in the lower hemisphere (*Pseudallescheria boydii*).*

The earliest known record of a mycotic infection is that in the Atharva Veda in India (about 2000–1000 BC), of mycetoma of the foot which was described under the name 'foot anthill.'

As a result of their visibility, the superficial mycoses of the mucosa or tegument have been known since antiquity. Hippocrates (460–377 BC) and Gallen (AD 130–200) described *aphthae albae* (in English called thrush, and in French *muguet* because of the whiteness of the infected tongue), whereas in 1847, Robin identified the yeast *Oidium (Candida) albicans* as the agent of thrush in infants (Robin 1853).

Celsus (first century AD), following the nomenclature of Hippocrates, dealt, in *De re medicina*, not only with thrush but described favus, the inflammatory lesions of some ringworm infections – kerion of Celsus. The first dermatophytic fungal infections were recognized only about 1840 by Remak, Schoenlein, and Gruby (Seeliger 1985, 1988).

The centrifugal growth of fungi in a circular form on the skin led to various names such as herpes (Greek: dandruff), now known as *herpes circinatus*. The Romans associated the lesions with insects and named the disease tinea, meaning any small insect larva. This name has remained in English clinical terminology (tinea capitis, tinea corporis, tinea pedis, etc.), and is translated in French as *teigne* and in popular English as ringworm. *Favus* (Latin: honeycomb), a specific chronic scalp

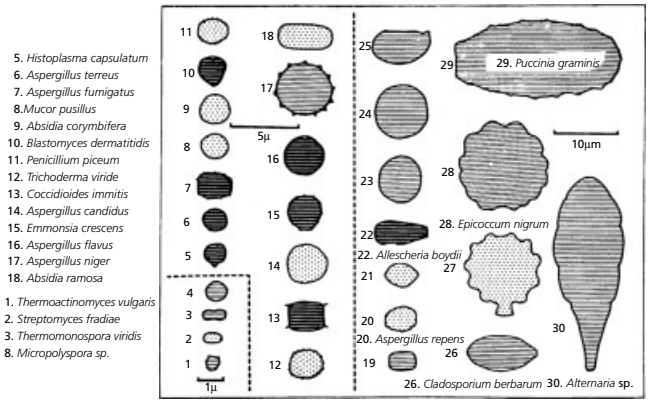

Figure 2 *Spores in allergies and mycoses of humans and other animals. Outlines of the airborne spores of Fungi and Actinomycetes causing allergies and mycoses. Directly pathogenic species – dark shading; allergenic species – light shading; species isolated from animal lungs – dotted. (Redrawn from Austwick 1966)*

mycosis, characterized by yellowish cup-shaped crusts (scutula) was the first human mycosis to be recognized as caused by a dermatophytic fungus by Remak and Schoenlein (Schoenlein 1839; Remak 1845); this discovery has been described by Seeliger (1985). Tinea imbricata, a tropical dermatophyte disease, easily recognized by the polycyclic, concentrically arranged rings of scales which are scattered over most of the body, was described by travellers in the Pacific Islands of Oceania. Dampier (1729) named it 'Tokelau disease' after the Islands where the disorder was prevalent. This disease was recognized also in southeast Asia, and it has been suggested that it may be of anthropological interest, as it was possibly introduced to the western coasts of South and Central America by pre-Colombian voyagers from Polynesia (Rippon 1988). Only in 1896 did Blanchard describe the agent as *Trichophyton concentricum* and later isolated cultures with difficulty.

The invention of the microscope during the last decade of the sixteenth century enabled seventeenth century microscopists, such as Hooke of England with his *Micrographia* London (1665), who presented the first illustrations of microfungi such as *Mucor*, followed by the Dutchman van Leeuwenhoek (1632–1723) and the Italian Malpighi (1628–94), in *Anatomia plantarum pars altera*, London, 1679, to give the first descriptions of some common microfungi. van Leeuwenhoek is credited with being the first person to have observed yeasts microscopically. In 1680 he sent descriptions and drawings of yeast cells to the Royal Society of London, 4 years after making public his observations on bacteria.

Aided by the binomial system of the Swedish physician and botanist Linnaeus (1707–78), descriptive mycology grew gradually, but steadily. Micheli (1679–1737), a Florentine botanist of the Public Gardens in Florence, was the first to give generic names to fungi that are now classified among the Hyphomycetes. His monograph *Nova plantarum genera* (published in Florence in 1729) was not only a historical milestone but also the starting point for mycology as a science. Familiar genera such as *Botrytis* and *Mucor* were described for the first time.

CONCEPT OF PATHOGENICITY

It required more than 200 years for a proposal of the concept of infectivity to be made. Fracastora of Verona (1546) postulated the existence of a *contagium vivum* as the cause of infectious diseases and foresaw a relationship between microfungi in nature and fungal diseases in humans and animals.

The first milestone in the medical mycological highway is attributed by most historians of medical mycology to the Italian, A. Bassi (1773–1856) (Ajello 1975a, 1993; Ainsworth 1976, 1986). In 1807, after he had studied 'physics, chemistry, natural history, some branches of medicine and the principles of mathematics,' Bassi began to study a devastating disease of the silkworm (*Bombyx mori*), the muscardine, and proved that it was caused by a fungus subsequently named, in his honor, *Beauveria bassiana*.

Bassi's revelation of the role played by a fungus in an animal disease inspired others to investigate the etiology of human diseases. Schoenlein and his assistant Remak succeeded in discovering, in 1837, the agent of the human favus, which was named *Achorion (Trichophyton) schoenleinii* by Remak (1845) in honor of his mentor Schoenlein (1793–1864), but the studies of Gruby (1810–98) proved to have a greater impact among the physicians at that time through his communications to the Academy of Sciences of Paris (1841–44) about the fungal origin of favus. For the first time, Gruby tried to reproduce a human infection by inoculating a colleague in the arm and also his own body with the fungus. He fulfilled Koch's postulates for the criteria of the etiology of infection 40 years before Koch had formulated them. In 1841, Gruby also described the in vivo appearance, in thrush, of the yeast named *Oidium (Candida) albicans* by Robin (Figure 3) in his doctoral thesis 6 years later (Robin 1847). Robin (1821–85), elected to the chair of histology at the University of Paris, made other important contributions to mycology, describing for the first time the dermatophyte *Trichophyton ('Microsporon') mentagrophytes* in his book published in 1853: *Histoire naturelle des végétaux parasites qui croissent sur l'homme et des animaux*. Gruby described an important agent of tinea capitis which he named *Microsporum audouinii* in honor of the great Parisian naturalist, V. Audouin (1797–1841), of the Paris Natural History Museum, known for his work on muscaridine disease. This is considered the second important historical milestone of medical mycology (Zakon and Benedek 1944). His microscopic descriptions (after his death more than 15 000 microscopic preparations and 2 000 photomicrographs were found among his possessions), interpreting host–parasite relationships, prepared the work of Sabouraud (Rook 1978). The role of fungi in these early concepts was preceded by the work of dermatologists such as W. Wilson (1817–84), J. Hoog (1817–99), T. Fox (1836–79), F. van Hebra (1816–80) of Vienna, and E. Bazin (1807–78); the last named wrote a thesis entitled 'La contagion et l'infection' (1839) and became a physician at the St Louis Hospital in Paris, publishing a monograph on ringworm in 1853.

Over several decades, pathogenicity was associated with the concept of spontaneous generation, and finally Pasteur succeeded in winning the fight against this concept of spontaneous generation of microorganisms – a theory that had been well established since antiquity. Pasteur (1822–95; Figure 4), unanimously recognized as the founder of microbiology, in the famous memoirs about the 'organised corpuscles existing in the atmo-

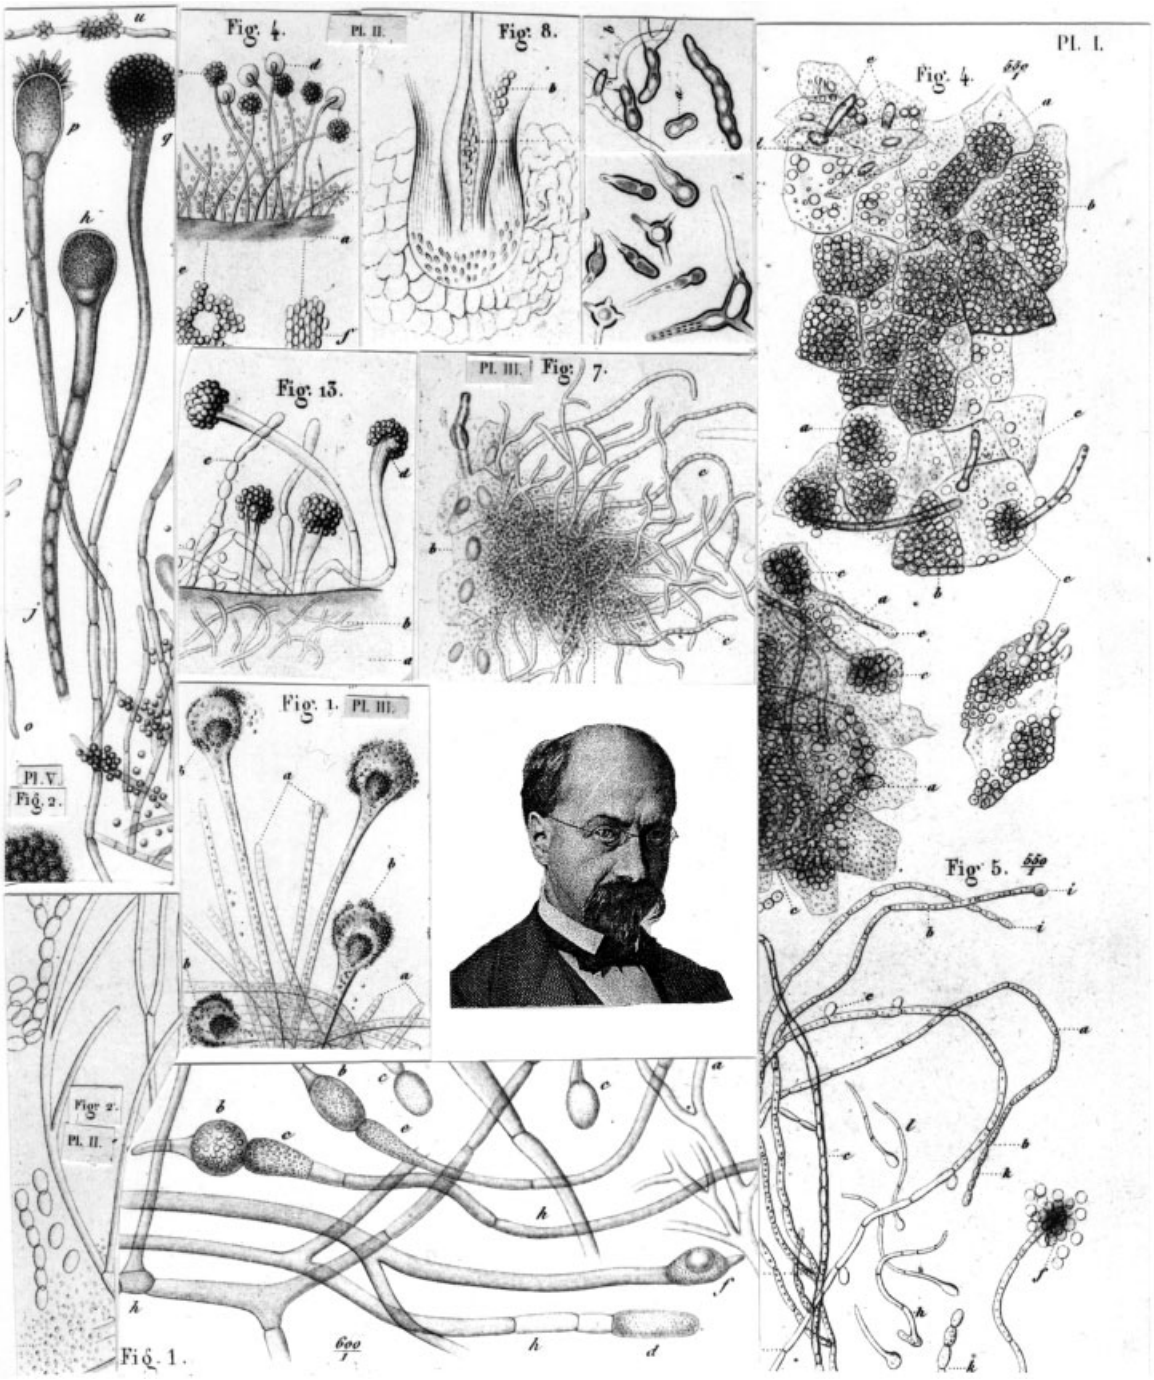

Figure 3 *Robin (1821–85), center, described and drew with tremendous detail the human and animal pathogenic fungi, observed in vivo ('d'après nature') on skin, oral, genital, digestive mucosae, ears, lungs, etc., in his book/atlas* Natural history of Plant's parasites of living humans and animals *(Robin 1853: 15 plates, 100 figures all detailed).* Oidium albicans *(for the first time the name of the thrush agent is specified) is represented as: clusters of yeast cells on epithelial cells and filaments which become entangled in depth; dermatophytes of tinea capitis with follicle invaded by spores on the inside and outside of hair; molds such as aspergilli in the auditory canal, lungs of ducks, or aerial sacs of other birds; and even mucorales in a bovine uterus.*

sphere,' reported his studies of air microorganisms collected in Paris and at 2 000 metres in Chamonix, near Mont Blanc. From his drawings, it is easy to recognize yeasts, yeast-like fungi (*Trichosporon*, *Geotrichum*), and filamentous fungi (*Penicillium*, *Mucor*, etc.) in the aerial biota, which later led to the science of aeromycology. His student, Miguel, made detailed studies for a doctoral thesis in 1883 about microorganisms present in the air, not only in the Paris Observatory, but also in dwellings, houses, and hospitals. The interest

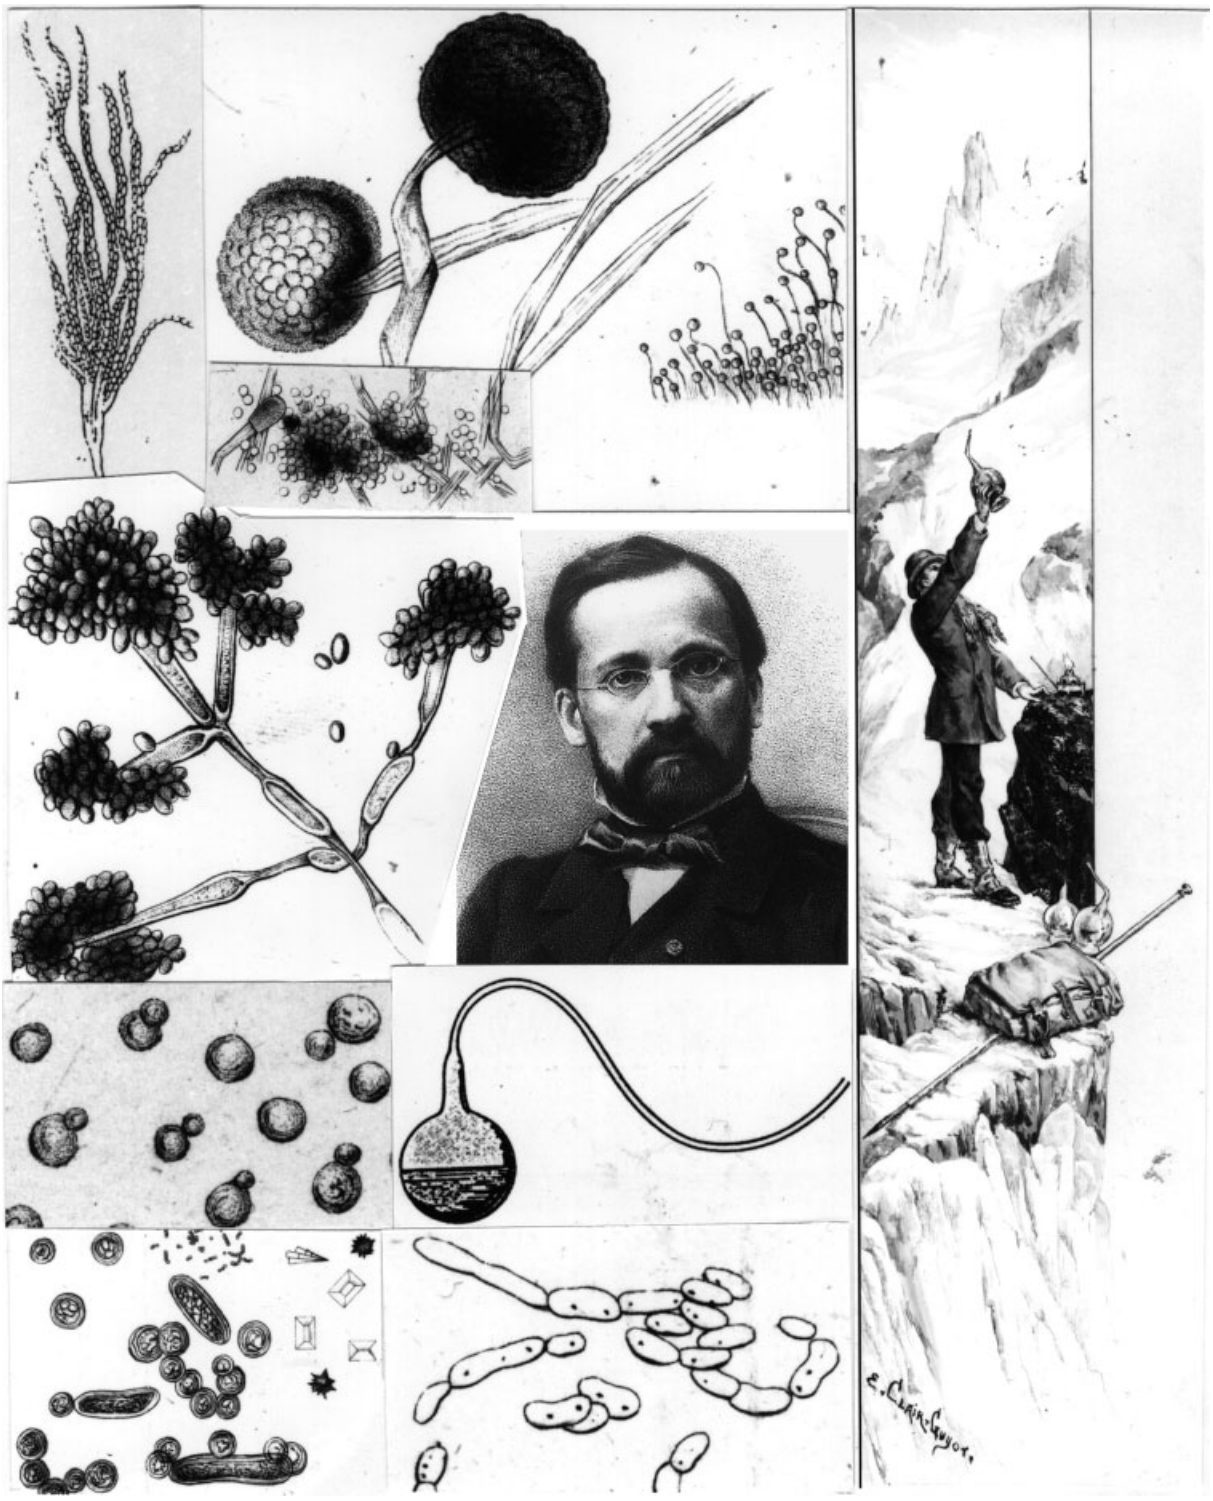

Figure 4 *Pasteur (1822–95), center, has drawn the 'organized corpuscles from the atmosphere' in the studies which came out against the theory of spontaneous generation (Pasteur 1861), illustrating the 'air spora' formed by filamentous and yeast-like fungi collected from the air of Paris and Chamonix in swan-neck flasks (at 2000 metres; aquarelle by Clair-Guyot, on the right).*

of Pasteur and his disciples in mycology was considerable. He revealed the role of yeasts in enzymatic fermentation, and he was the first to describe dimorphism in such filamentous fungi as *Mucor* spp., which transformed into a yeast-like form, and to improve culture media.

Jules Raulin (1836–96), van Tieghem (1839–1914), and Duclaux (1840–1904) were the first three students

to work with Pasteur in his laboratory at the Ecole Normale in Paris in the early 1860s. Raulin's study was designed to elucidate the mineral nutrition of *Aspergillus niger* by quantitative measurement of the growth obtained in recognition of the importance of trace elements for the culture of fungi. The controversy between Pasteur and Leibig, about the size of inoculum necessary for the growth of yeasts, led to the bios of Wildiers, and the growth factors known as vitamins.

van Tieghem and Le Monnier (1873) introduced the microscopic examination of hanging drop cultures of fungi (Figure 5) – the 'van Tieghem cell;' they described the genus *Absidia* in 1876 and the species *Mucor circinelloides* in 1875. In 1887, the German Petri invented the 'Petri dish' – the covered glass plate in which the solid support of gelatine or agar allowed the culture of bacteria and fungi; this led to the greater development of bacteriology and mycology (Petri 1887).

Sabouraud (1864–1938), a young dermatologist at the St Louis Hospital, started his studies on dermatophytes in 1890 with the famous 'Great Course of Microbiology' inaugurated by Roux 2 years after the foundation of the Pasteur Institute (1888), at the end of Pasteur's historical career. This explains Sabouraud's studies on the culture of dermatophytes. Duclaux (1886) described an enzyme (zymase) in a dermatophyte (*Trichophyton tonsurans*) and discredited the opinion held by some of his predecessors and contemporaries that all dermatophytoses were caused by a single fungal species, a mutable *Aspergillus* or *Penicillium* species. Pure cultures were needed for the identification and definition of fungus species on solid taxonomic grounds, and to reveal the existence of a multiplicity of pathogenic species; this was realized by Sabouraud.

Other milestones in the history of medical mycology continued in the 1880s, 1890s, and 1900s, with the discovery of the principal agents of systemic and subcutaneous mycoses and with the evolution of the diseases that they provoked.

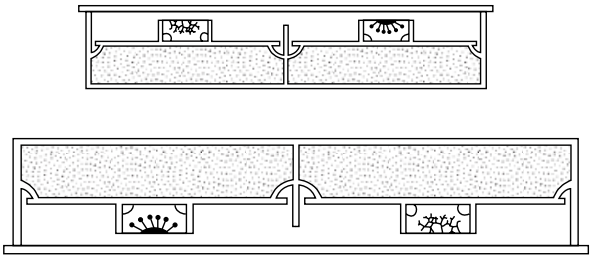

Figure 5 *The 'van Tieghem cell.' (From van Tieghem and Le Monnier 1873)*

HISTORY OF THE PRINCIPAL FUNGI RESPONSIBLE FOR MYCOSES

Dermatophytes and dermatophytoses: essential milestones in the history of medical mycology

The history of the tineas and their agents, the dermatophytes, started with Sabouraud in his mongraph, *Les Teignes* in 1910. The history was continued by Ainsworth (1976, 1986), Ajello (1974, 1975a), Emmons et al. (1963, 1970, 1977), Seeliger (1985, 1988) and later Rippon (1988). They outlined the evolution of our knowledge of this important group of mycoses and their etiological agents.

The work of Sabouraud is one of the most important milestones in the history of medical mycology. He truly revolutionized our concepts about dermatophytes and significantly contributed to the development of medical mycology. He studied medicine in Paris, was a man of multiple talents and an excellent dermatologist. He was also a talented sculptor. He trained in microbiology at the Pasteur Institute under Roux and so knew pure culture techniques. His studies, which started in 1892, culminated in 1910 in the publication of his classic book *Les teignes* (Sabouraud 1910), the most comprehensive account of all the then-known dermatophytes, to which mycologists still refer. He published 1 000 scientific papers and 12 huge volumes. His work was acknowledged at the dermatology hospital, the St Louis Hospital, by the creation of a laboratory for dermatophyte infections and a Children's School for the treatment and education of children suffering from tinea capitis, a severe, chronic disease that was difficult to treat at that period. He used pure culture techniques and new media to determine the physiological and morphological characteristics and parasitological aspects of the development of dermatophytes in vivo, and observed variations and pleomorphism in dermatophytes. Sabouraud laid down a solid foundation for modern medical mycology, and consequently the journal of the ISHAM was initially named *Sabouraudia* (1961). His medium for the identification of the dermatophytes still bears his name and is universally used.

Sabouraud developed a classification system, based on the in vitro and in vivo characteristics of dermatophytes, which remains valid for the three genera *Epidermophyton*, *Microsporum*, and *Trichophyton*, but not for the genus *Achorion*. The last was invalidated by Emmons (1934; Figure 6), based on the botanical rules of nomenclature and taxonomy. Many of the common dermatophytoses and dermatophytes in humans were first differentiated in Sabouraud's time: in 1902 Bodin described *T. violaceum*; Castellani and Chalmers (1910) described *T. rubrum* (as *E. rubrum*); Sabouraud (1910) proposed the name *E. inguinale* for the fungus respon-

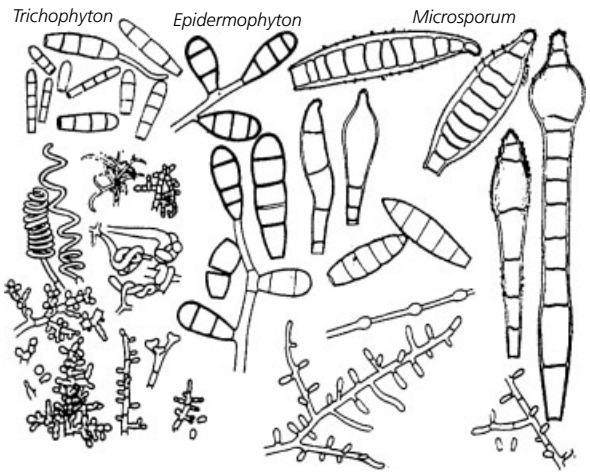

Figure 6 *Drawings from Emmons (1934): dermatophytes. Natural groupings based on the form of conidia and accessory organs.*

sible for tinea cruris (now *E. floccosum*); the Hebra's eczema marginatum described in 1860; and also *T. persicolor* (1902) now classified in the genus *Microsporum*. Animal dermatophyte infections included ringworm of cattle (*T. verrucosum* Bodin 1902), of horses (*T. equinum* Matruchot and Dassonville 1898), of cats, dogs, and humans (*Microsporum canis* Bodin 1902), and of fowl (*Microsporum gallinae* as *E. gallinae* by Megnin in 1881). Other dermatophytes were discovered, such as *M. ferrugineum* Ota 1921, long considered to be a *Trichophyton* species, until typical echinulate macroconidia were obtained by Vanbreuseghem et al. (1970). This mold is found in Japan and the Far East and is responsible for tinea capitis.

In the years after Sabouraud, various tentative modifications of his generic classification were suggested, especially by Langeron (1874–1950) of the Faculty of Medicine of Paris, Vanbreuseghem (1909–93), who developed the field of medical mycology in Belgium after studying with Langeron, and Rivalier (1892–1979), who became the Director of Sabouraud's Laboratory at the St Louis Hospital. Many mycologists adopted Sabouraud's classification, which was simplified by Emmons (1934; see Figure 6). In 1954, Conant who had worked with Sabouraud (1936–37) also modified his classification (Conant 1936a, b, 1937a).

Langeron and Milochevitch (1930) emphasized the importance of natural media to induce the characteristic sporulation of dermatophytes. Studies on the nutrition of dermatophytes, as related to morphogenesis in chemically defined synthetic or semisynthetic media, were carried out after 1950, essentially by Georg (Georg 1950; Georg and Camp 1957), Drouhet and Mariat (1952a, 1953), Drouhet (1952), and Silva and Benham (1952). The need was demonstrated for vitamins and amino acids as essential or complementary growth factors for certain groups of dermatophytes which were strictly adapted to human or animal hosts. The capacity for sporulation was lost in media without the addition of exogenous growth factors. These biochemical and physiological studies led to routine nutritional tests for the specific identification of dermatophytes (Georg and Camp 1957).

The introduction by Vanbreuseghem (1952) of the hair-baiting technique, for the specific purpose of isolating dermatophytes from soil, revealed the worldwide occurrence of dermatophyte-like fungi and geophilic dermatophytes, as studied and reviewed by Ajello (1974, 1975a) and Rippon (1988).

The next major development in the taxonomy of dermatophytes came in 1959 with the description of the teleomorph, the perfect or sexual stage of *Trichophyton (Keratinomyces) ajelloi* by Dawson and Gentles (1959) under the name *Arthroderma uncinatum*.

Nannizzi (1877–1961) of the University of Sienna (Italy) had, in 1927, described the sexual state of *Microsporum gypseum* as *Gymnoascus gypseum* (Figure 7). In 1960, just before his death, Griffin reisolated the perfect stage of *M. gypseum* from Australian soil. Independently, in 1961, Stockdale (1927–89), of England's Commonwealth Mycological Institute, discovered several teleomorphic stages of this dermatophyte and proposed the new genus *Nannizzia* to accommodate the teleomorphs of the *Microsporum* spp. (Stockdale 1961, 1963, 1967; Hasegawa and Usui 1975). Nannizzi's remarkable breakthrough was not recognized by some medical mycologists at that time because the substrates used were erroneously considered not to be sterile. Since then, numerous imperfect or anamorphic species have been found to have one or more ascigerous states obtained in pure culture with cycloheximide [the introduction of cycloheximide (Acti-Dione) in the selective isolation of pathogenic fungi to humans by Georg et al. (1954) contributed to the discovery of numerous dermatophytes in their sexual states]. The seminal work of

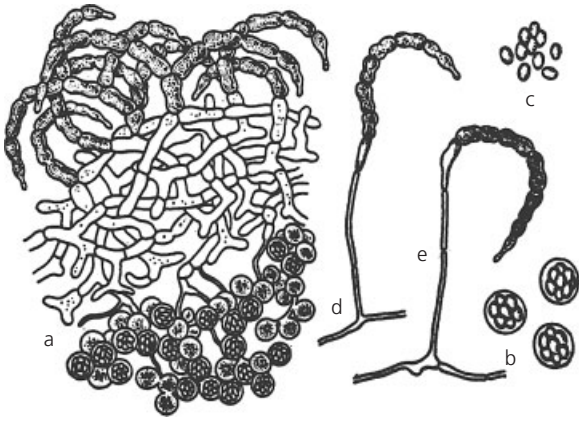

Figure 7 Gymnoascus gypseus Nannizzi, *teleomorphic state of* Microsporum gypseum *(Nannizzi 1927). Stockdale described several teleomorph states for* Microsporum gypseum *and created the genus* Nannizzia *in honor of Nannizzi (1877–1961).*

Nannizzi was unanimously recognized (Rippon 1985; Ajello 1993). The perfect state was discovered for common dermatophytes such as *Microsporum canis*, named *Nannizzia otae* in honor of the famous Japanese mycologist Ota (Hasegawa and Usui 1975). All of the teleomorphs of dermatophytes and dermatophyte-like fungi were classified into two genera until 1986, when Weitzman et al. proposed treating *Nannizzia* as a later synonym of the genus *Arthroderma*. Currently, the use of physiological characteristics, mating types, mitochondrial DNA, scanning and transmission electron microscopy, and antigenic analysis, based on monoclonal antibodies, in addition to classic methods of descriptive mycology, has given the taxonomy of dermatophytes and other pathogenic fungi a firm scientific basis (Tanaka et al. 1992) (see also Fungal structure and morphology).

The combination of improved hygiene and the revolutionary application of griseofulvin in 1958 in the treatment of dermatophytoses decreased the prevalence of tinea capitis in occidental regions, although this disease remains prevalent in some tropical areas. On the other hand, although unknown in Sabouraud's era, tinea pedis caused by *Trichophyton rubrum* of Asian origin has now spread worldwide.

Dermatophyte-like infections

Ringworm-like nondermatophyte infections (skin, nails) caused by pheoid (black) fungi of tropical origin, such as *Hendersonula (Nattrassia) toruloidea* Nattrass 1930, *Scytalidium hyalinum* Campbell and Mulder 1977, have been described in Europe (Gentles and Evans 1970; Hay and Moore 1984), as well as some tropical superficial mycoses known for numerous years as hair colonizers: white piedra caused by *Trichosporon beigelii* (1887), black piedra caused by *Piedraia hortai* (1913) and the skin lesion, tinea nigra, caused by *Exophiala (Cladosporium) werneckii* (1921). Since their discovery, these superficial dermatomycoses represent a rare group of cutaneous mycoses.

OPPORTUNISTIC YEASTS AND FILAMENTOUS FUNGI AS AGENTS OF DEEP SYSTEMIC OR VISCERAL MYCOSES

Opportunistic fungi and opportunistic fungal infections: predisposing factors

These new terms have been introduced into medical mycology since the International Symposium on opportunistic infections in 1962, as emphasized by Ajello, Baker, Emmons, Segretain, Utz, and other participants at that historical meeting. These mycoses have increased progressively and intensively as a result of the favorable factors for opportunistic fungal infections which have evolved over the past decades (Emmons 1962).

INTRINSIC FACTORS DEPENDENT ON THE HOST

Apart from physiological factors resulting from age, pregnancy, immunological and/or endocrinological conditions, the pathological factors are most important. For a long time it has been known that normally saprophytic fungi may invade patients with severe, debilitating, primary diseases such as diabetes, malignant blood diseases, Hodgkin's disease, and various neoplasms. However, before the advent of antibiotic and corticosteroid treatments, opportunistic mycoses were found only in patients in the final stages of serious microbial infections, severe diabetes, other endocrinopathies or malignant diseases (Emmons et al. 1963, 1970, 1977; Drouhet 1972; Warnock and Richardson 1982, 1991; Armstrong 1981). At present, these secondary opportunistic fungal infections are extremely common in immunocompromised hosts, particularly those with granulocytopenia below 1 000 cells/ml. *Candida* spp. infections are seen as sequels to antibiotic treatment. Sometimes fungal infections are diagnosed before the primary disorder and the mycoses become indicative 'signal' diseases such as cryptococcosis. The occurrence of opportunistic fungal infections has risen progressively (Drouhet 1972; Fraser et al. 1979; Bullock and Deepe 1989). Invasive fungal infections have been reported in recent years in 26 percent of patients who are chronically and intensively immunosuppressed as a result of underlying disease or drug therapy. The incidence of aspergillosis increased from 1.91 to 4.8 per million persons (+ 158 percent). *Cryptococcus neoformans* infections increased from 1.3 per million to 2.3 per million (+ 78 percent) between 1970 and 1976 in the USA. However, the incidence rate became substantially higher after 1980 as a result of the opportunistic infections, cryptococcosis, candidiasis, and histoplasmosis, which occur in AIDS (Graybill 1988; Dupont et al. 1994; Stevens et al. 1994).

Alterations of the immune system

The pathogenesis of fungal infections in the immunocompromised host has recently been reviewed and discussed in the general context of microbial infections. Nonspecific immune mechanisms, including cellular and humoral ones, and specific cell-mediated and humoral immunity play important but unequal roles in host resistance to fungal infections (Warnock and Richardson 1982, 1991; Murphy et al. 1994).

Functional defects in chemotaxis

Adherence, or killing (degranulation), phagocytic disorders caused by low cell numbers, granulopenia, and

disorders of leukocyte metabolism are often correlated with fungal infections such as aspergillosis, candidiasis, and other opportunistic mycoses (Waldorf 1986; Walsh et al. 1994).

Acquired immunodeficiency syndrome

Severe fungal opportunistic infections have been reported in the USA, Europe, Africa, and other countries (Chandler 1985; Drouhet and Dupont 1990; Dupont et al. 1994). Usually candidiasis, particularly thrush and esophagitis (Gottlieb et al. 1981; Klein et al. 1984; Tavitian et al. 1986; Dupont and Drouhet 1988), cryptococcosis (Kovacs et al. 1985; Dupont 1989; Drouhet and Dupont 1990) and histoplasmosis (Graybill 1988; Mackenzie 1992), are observed because natural resistance to these infections relies on cell-mediated immunity. Other opportunistic infections in the immunocompromised host, such as disseminated aspergillosis, were very rare in acquired immunodeficiency syndrome (AIDS) in the 1980s, because their development correlates with the absence or reduced function of polymorphonuclear leukocytes. The mycosis with the highest incidence in AIDS, between 50 and 90 percent, is oral and esophageal candidiasis. In high-risk patients, the presence of unexplained oral candidiasis predicts the development of serious opportunistic infections more than 50 percent of the time. Cryptococcosis is the most dramatic fungal infection in AIDS. In the USA, out of 13 834 AIDS patients registered by the Centers for Disease Control (CDC) in October 1985, 904 cases of cryptococcosis (6.5 percent) were diagnosed. In France during the years 1985–95, most of the 1 300 diagnosed cases of cryptococcosis developed in AIDS patients. Although histoplasmosis may occur in immunocompetent patients, we wonder, as do other authors, whether it should not be considered one of the major deep infections in those patients with AIDS who have resided in an endemic area.

A new candidate for systemic mycosis has appeared in AIDS – infection caused by *Penicillium marneffei*, an Asian tropical fungus described in 1956 by Capponi et al. which was responsible for a mycosis of the reticuloendothelial system in Vietnamese bamboo rats, and for an accidental human infection (Capponi et al. 1956; Segretain 1959). Since 1987, human cases of disseminated, pulmonary, cutaneous penicilliosis caused by *P. marneffei* have been observed in England, France, Italy, and the USA, in AIDS patients who travelled in southeast Asia or autochthonous patients with AIDS living in China, Hong Kong, and Thailand. The 44 cases reported in patients positive for the human immunodeficiency virus (HIV) traveling or living in southeast Asia during 1985–93 increased to 117 cases in the following 2 years and to more than 400 cases in 1995 (Drouhet 1993a; Supparatpinyo et al. 1994; Drouhet and Dupont 1995) (see also Penicilliosis).

The pattern of mycotic infection in AIDS patients has been radically altered by the introduction of combination antiretroviral chemotherapy.

EXTRINSIC, IATROGENIC FACTORS

These include effects caused by either drug treatment or breach of the integument resulting from medical (vascular catheters for drug administration or parenteral nutrition and other catheters) and surgical (organ transplants, abdominal surgery, etc.) devices or interventions, which allow the penetration of opportunistic fungi.

Antibiotics

The role of antibiotics in the pathogenesis of infections with *Candida* spp. is based not only on yeast selection in the alimentary canal and mucous membranes (imbalance between the bacterial and yeast biota), but also on the action of antibiotics on the immunological defence systems (Drouhet 1972). The latter includes decreased antibody production, suppression of phagocytosis, and metabolic alteration of the host cells. Recent data indicate that antibiotics acting against bacteria augment the adhesion of *C. albicans* to the surface of epithelial cells by mannan receptors taking the unoccupied place of the bacteria that disappeared, thereby facilitating the transition of *C. albicans* from the yeast form to its filamentous aggressive form (Kennedy 1988; Kennedy et al. 1992). This was demonstrated both in vivo and in vitro in a few hours and may explain the remarkable in vivo activity of azoles, such as ketoconazole, which arrest mycelial but not yeast cell development at very low concentrations (Borgers and Vanden Bossche 1982).

Immunosuppressants

Corticosteroids, immunosuppressants (such as azathioprine, cyclophosphamide, cyclosporin, etc.) and cytostatic agents favor the development of opportunistic fungal infections. The granulopenia induced by these drugs is responsible for susceptibility to the invasive forms of deep mycoses (Odds 1988). In the 1960s and 1970s, major renal transplant units reported fungal fatalities of up to 15 percent and up to 30 percent in heart transplant recipients (Warnock and Richardson 1991).

Intravenous drug abuse

Heroin addicts are a population at risk for certain infectious diseases, such as bacterial and fungal endocarditis, and hepatitis B. Since 1980, a new pathological septicemic syndrome of *C. albicans* infection, characterized by fever followed immediately by cutaneous disseminated lesions of folliculitis, pustulosis, subcutaneous nodules, and ocular metastasis, and several weeks later by osteoarticular involvement, was observed in the brown heroin addict population. This was observed not

only in France (Drouhet et al. 1981; Drouhet and Dupont 1983; Dupont and Drouhet 1985) where more than 200 cases occurred, but also in Italy and principally in Spain (> 890 cases) and even in Australia. Although crude heroin or Iranian or Asian brown heroin does not contain *C. albicans*, the yeast is introduced by the syringes used by the addicts, which are contaminated from the spoon in which the heroin is dissolved in lemon juice. All patients have oral and digestive tract candidiasis as the primary source of this contamination. Alterations of T- and null-lymphocyte frequencies in the peripheral blood of opiate addicts were observed; these result from the opiate receptor sites on T lymphocytes. An immunosuppressive of the cellular immunity contaminant of brown heroin may also have been the origin of this new pathology, which is unknown in the USA where white or purified heroin is used.

Desferrioxamine

Therapy for iron or aluminum overload in dialyzed patients, with desferrioxamine, has become an important predisposing factor, since 1986, for disseminated severe zygomycosis caused by *Rhizopus* spp. (Kwon-Chung and Bennett 1992).

Candida spp. and candidoses

What is extraordinary in the history of *C. albicans*, and the 10 major pathogenic thermophilic *Candida* spp. adapted to warm-blooded animals including humans, is that these unicellular fungi, which have been recognized in the past 130 years, are capable of showing up multiple new conditions in all branches of medicine. The notion of the 'compromised' patient was developed by the famous French pediatricians Trousseau (1868) and Parrot (1869a, b) who revealed that athrepsy in newborn infants may lead to disseminated thrush of the digestive and pulmonary tracts (Figure 8a). The first description by Parrot (1869a, b, 1877) of esophageal, gastric, intestinal, laryngeal, tracheal, and pulmonary thrush, initiated by oropharyngeal thrush, was histologically proven to be a clinical entity (Figure 8b). In the first edition of his monumental book *Candida and candidosis* published in 1979, Odds analyzed 2 265 references, but in the second edition (1988) no fewer than 5 796 references were cited. This emphasized the many developments that have occurred in the molecular, medical, and genetic aspects of *C. albicans* and candidiasis (Kwon-Chung et al. 1985; Whelan 1987; Lott et al. 1992; Odds 1994).

Thrush, an important opportunistic marker in AIDS patients (Gottlieb et al. 1981; Klein et al. 1984; Tavitian et al. 1986), is a clinical manifestation caused exclusively by *C. albicans*. The other forms of candidiasis can be produced by various other *Candida* spp. The superficial manifestations of candidiases are conventionally separated from deep-seated, disseminated or systemic candidiasis, which now principally appears in iatrogenic conditions, but the boundary is difficult to establish between the two forms (Bodey and Fainstein 1988, 1993).

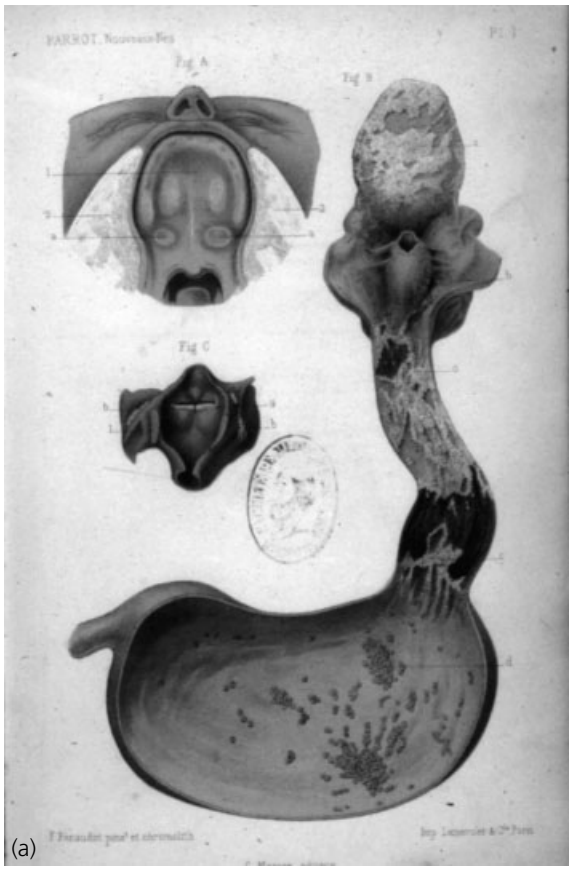

Figure 8 *Drawings of Parrot (1869a) showing* **(a)** *the clinical aspects of generalised thrush in sick newborn infants with white patches on the tongue, esophagus, gastric mucosa, larynx (even bronchi and lungs, not shown here). (Continued over)*

Chronic mucocutaneous candidiasis (CMC), characterized by recurrent and persistent infections of the mucosa, nails, and skin by *C. albicans,* can be observed in patients with cellular immune abnormalities (Kirkpatrick et al. 1971). It has been shown that some of these abnormalities may be primarily induced by the mannan antigen of *C. albicans* (Durandy et al. 1987). The elimination of this immunosuppressive antigen by intensive antifungal therapy (amphotericin B, ketoconazole) restores the impaired cell-mediated immunity to *C. albicans* and leads to the disappearance of severe, chronic skin lesions (Drouhet and Dupont 1980, 1983; Drouhet et al. 1985).

The incidence of candidiasis has increased annually since the introduction of antibiotic therapy, immunosuppressive therapy, and other conditions. Odds (1988), basing estimates on official statistics and publications in four countries over a period of 30–35 years starting in

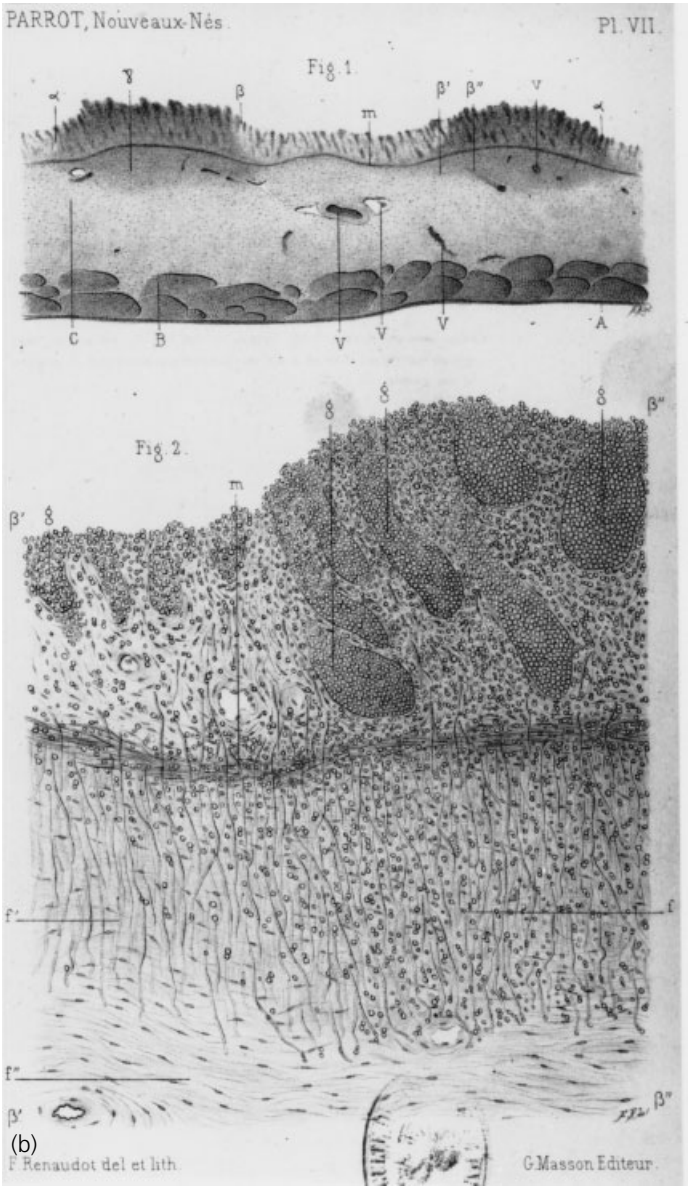

Figure 8 *Drawings of Parrot (1869a) showing* **(b)** *Histological aspect of* Candida albicans *yeast cells on the epithelial digestive mucosa with deep penetration by filaments ('aggressive form') into submucosal and muscular strata (explaining septicemia). The famous pediatricians Trousseau and Parrot at that time had described systemic candidiasis (Continued).*

1950, showed that, in the USA, the number of deaths attributed to candidiasis has increased roughly threefold between the late 1960s and the late 1970s; in France there has been a twofold increase between 1973 and 1982. During the 1980s and 1990s, the incidence of fungemia caused by *Candida* spp. acquired in hospitals increased more than threefold. Finally, adherence of *Candida* spp. to host surfaces was shown to be an important feature in the pathogenesis of candidiasis, and biomolecular studies about adherence accordingly developed rapidly (Kennedy et al. 1992; Robert et al. 1992) (see also Candidiasis).

Lipophilic yeasts and malasseziasis

The history of lipophilic yeasts grouped in the genera *Malassezia* Baillon 1889, and *Pityrosporum* Sabouraud 1904 are now unified in a single genus *Malassezia* (Guého and Meyer 1988). Their clinical manifestations – pityriasis versicolor, pityriasis capitis, and seborrheic dermatitis – are among the most interesting in medical mycology. Eichstedt (1846) and Sluyter (1856) termed the disease pityriasis versicolor as a result of the yellow–brown or achromic macules (*pityron* = bran or scale forming in Greek). In 1853, Robin observed the

spherical budding cells grouped in clusters associated with hyphae and named the agent *Microsporon furfur*. Rivolta (1873) considered it to belong to *Cryptococcus*, but Malassez (1974) clearly described the yeast-like cells from scalp scales and dandruff (pityriasis simplex capitis) as spores. Bizzozero, in 1884, observed the morphological diversity in the epidermal scales, and named the organisms with spherical cells *Saccharomyces sphaericus* and those with oval cells *S. ovalis*. In 1889, Baillon in his *Traité de botanique* created the generic name *Malassezia* and named the agent of pityriasis versicolor *Malassezia furfur*. Matakieff (1899) drew the sculpting of the cell wall, showing spiral grooves and branching hyphae in the scales of pityriasis versicolor (Figure 9a). These aspects were confirmed more recently using electron microscopy (Guillot et al. 1995) (Figure 9b). Sabouraud (1904) individualized clearly the 'scaling dermatoses' such as pityriasis capitis (dandruff) and seborrheic dermatitis (Figure 10) – a dermatologically complex subject of controversy (see Hay and Midgley 1988). He also created the genus *Pityrosporum*, with *P. malassezi* being distinct for him from the dimorphic agent of pityriasis versicolor. Attempts to elucidate the role of yeasts in these scaling dermatoses were hindered by difficulties in culturing the lipophilic organism and determining its exact growth requirements, until studies by Benham (1939) and Gordon (1951). The first culture of this yeast was obtained in the presence of lipids by Ota and Huang (1933). The polymorphism of *M. furfur* led Gordon to separate *P. orbiculare*, considered to be the etiologic agent of pityriasis versicolor, and *P. ovale* related to pityriasis capitis and seborrheic dermatitis as Sabouraud had claimed in 1904. There followed a long series of studies favoring this proposition, but these were contradicted by others (reviewed by Midgley 1989). In 1925, Weidman isolated a yeast from a severe exfoliative dermatitis of an Indian rhinoceros (*Rhinoceros unicornis*), which he cultured without the addition of lipids; he named it *P. pachydermatis*. Later, it was described as *P. canis*, by Gustafson in 1955. This species is largely observed in dogs. Studies on the ultrastructure and genomic structure confirm the validity of three species: *M. furfur* (*M. furfur* biovar. *orbiculare* and *M. furfur* biovar. *ovale*), *M. pachydermatis*, and *M. sympodialis* (Guého et al. 1987, 1994; Guého and Meyer 1988; Simmons and Guého 1990). This new classification has recently been extended further. An experimental model of Malassezia infection reproduced seborrheic dermatitis (Drouhet et al. 1980, 1988b) with follicular and cutaneous invasion in guinea pigs and mice, as shown by Sabouraud in 1904 (Figure 10). The therapeutic activity of topical azoles, and particularly of oral ketoconazole, led to the cure of pityriasis capitis, seborrheic dermatitis, and pityriasis versicolor. Clinical studies have shown the important role of lipophilic yeasts in folliculitis after antibacterial and corticosteroid therapy, and in AIDS (Drouhet and Dupont 1990; Hay 1991) as well as in septicemia and systemic malassezia infection in preterm newborns receiving parenteral lipid hyperalimentation (Dankner et al. 1987; Guého et al. 1987) (see also Superficial diseases caused by *Malassezia* species).

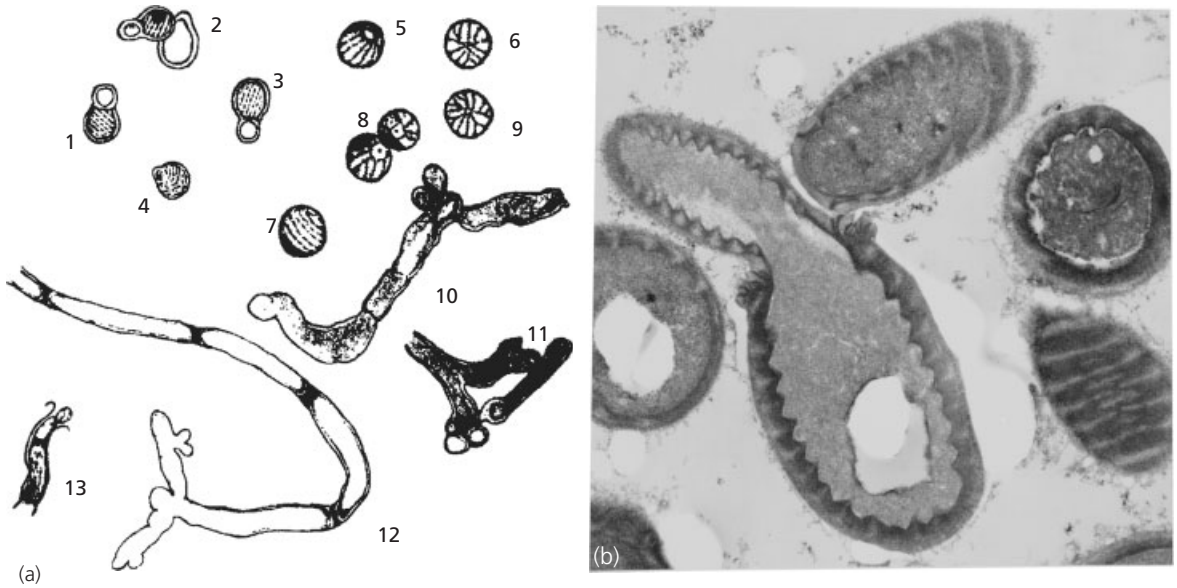

Figure 9 (a) *From Matakieff (1899): sketches 1–9 took into account the sculpturing of the innermost layer of the yeast's cell wall; sketches 10–12 illustrated budding and branching hyphae in scales of pityriasis versicolor; sketch 13 showed the purported formation of endospores.* **(b)** *Ultrastructure of the serrated cell wall of the yeast* Malassezia *showing growths on the plasma membrane as Matakieff had observed almost 100 years ago with an ordinary microscope. Cryptococcus neoformans and cryptococcosis

In 1894, the Italian microbiologist Sanfelice isolated an encapsulated yeast-like fungus, from peach juice, which he named *Saccharomyces neoformans* because of the pseudotumoral, sarcoma-like, lymphadenitic lesions observed in animals after intraperitoneal inoculation (Sanfelice 1895). At the same time, in Germany, a pathologist, Busse (1894, 1895), and a surgeon, Buschke (1895), separately reported the same fungus from sarcoma-like lesions of the tibia, and cutaneous and other lesions in a 31-year-old woman; they drew different aspects of the capsulated yeast including pseudomycelial or moniliform cells (Figure 11) in addition to histopathological cellular reactions (Figure 12). In 1896, in France, Curtis described a similar case using the term human saccharomycosis for the observed disease and he called the organism *Saccharomyces subcutaneous tumefaciens*. This second human case of cryptococcosis was retrospectively considered to be *Cryptococcus neoformans* var *gattii*, serotype B. When, in 1901, the eminent French mycologist Vuillemin (1861–1932) from Nancy examined several cultures, he did not find ascospores characteristic of the genus *Saccharomyces* and named it *Cryptococcus* – a name used earlier in 1833 by Kutzing. Therefore, he reclassified the yeast isolate of Busse and of Curtis into the genus *Cryptococcus* and the isolate of Sanfelice (1894, 1895) as *C. neoformans*. Subsequently, several cases were reported, especially in Europe, but the disease was confused with blastomycosis, so it was known as European blastomycosis. In 1905 Von Hansemann was the first to observe this fungus in meningitis. In 1916, Stoddard and Cutler described the clinical aspects of the disease. Ignoring the European literature, the authors mistook the mucoid capsule of the yeast for histolysis of host tissue, and therefore named the fungus *Torula histolytica*. Unfortunately, this name became popular in the Anglo-Saxon literature, and the disease was known for a long time as torulosis or torula meningitis, until the terms of Vuillemin (1901) – *C. neoformans* and cryptococcosis – became widely used in medical mycology. In 1935, Benham clearly differentiated cryptococcosis from the 'blastomycoses,' especially from blastomycosis (caused by *Blastomyces dermatitidis*), by studying numerous strains of cryptococci. She showed that only one species was responsible for cryptococcosis, although serological differences existed among the strains (Benham 1935, 1950). Benham is considered to be one of the most remarkable women pioneer scientists in medical mycology (O'Hearn 1985).

An important step in the history of this fungus was the discovery in 1951 by Emmons of *C. neoformans* in barnyard soil and in 1955 the frequent saprobic association with nests and droppings of pigeons (Emmons 1955). Although it was known that *C. neoformans* was isolated from a peach by Sanfelice in 1894, during the following 55 years isolation of this fungus was only obtained from humans and lower animals, so an endogenous source of infection was erroneously assumed. Since these discoveries, the epidemiology of cryptococcosis has been intensively studied and the role of other plant sources such as *Eucalyptus* species acknowledged.

Another important step originated from the studies of the capsular polysaccharides of *C. neoformans*. In 1950, Drouhet et al. showed that the principal capsular polysaccharide of *C. neoformans* was a glucuronoxylomannan, a virulence factor that inhibits the migration of leukocytes (Drouhet and Segretain 1951). Since then numerous studies, particularly by Bulmer and Sans (1967, 1968), showed the interrelationships of the polysaccharide capsule, phagocytosis and the mechanism of host defence against *C. neoformans*. The quantity of capsular polysaccharide in the host may be so great that it can be found as a free, circulating antigen in body fluids and easily detected by a latex agglutination test (Bloomfield et al. 1961). Evans, in 1950, identified three serotypes (A, B, and C), and in 1951 confirmed that glucuronomannan is the predominant capsular polysaccharide, but also found the presence of galactose (Evans and Kessel 1951), to which a fourth serotype D was added by Wilson et al. (1968), on the basis of antigenic differences in capsular polysaccharides. The historical Sanfelice's strain (CBS 132 = ATCC 32045) belongs to serotype D, Busse's strain (CBS 879 = ATCC 4189) to serotype A, and Curtis' strain (CBS 1622 = ATCC 2344) to serotype B.

The observation that pigeon droppings were a nutrient source led Staib (1963), from the Koch Institute in

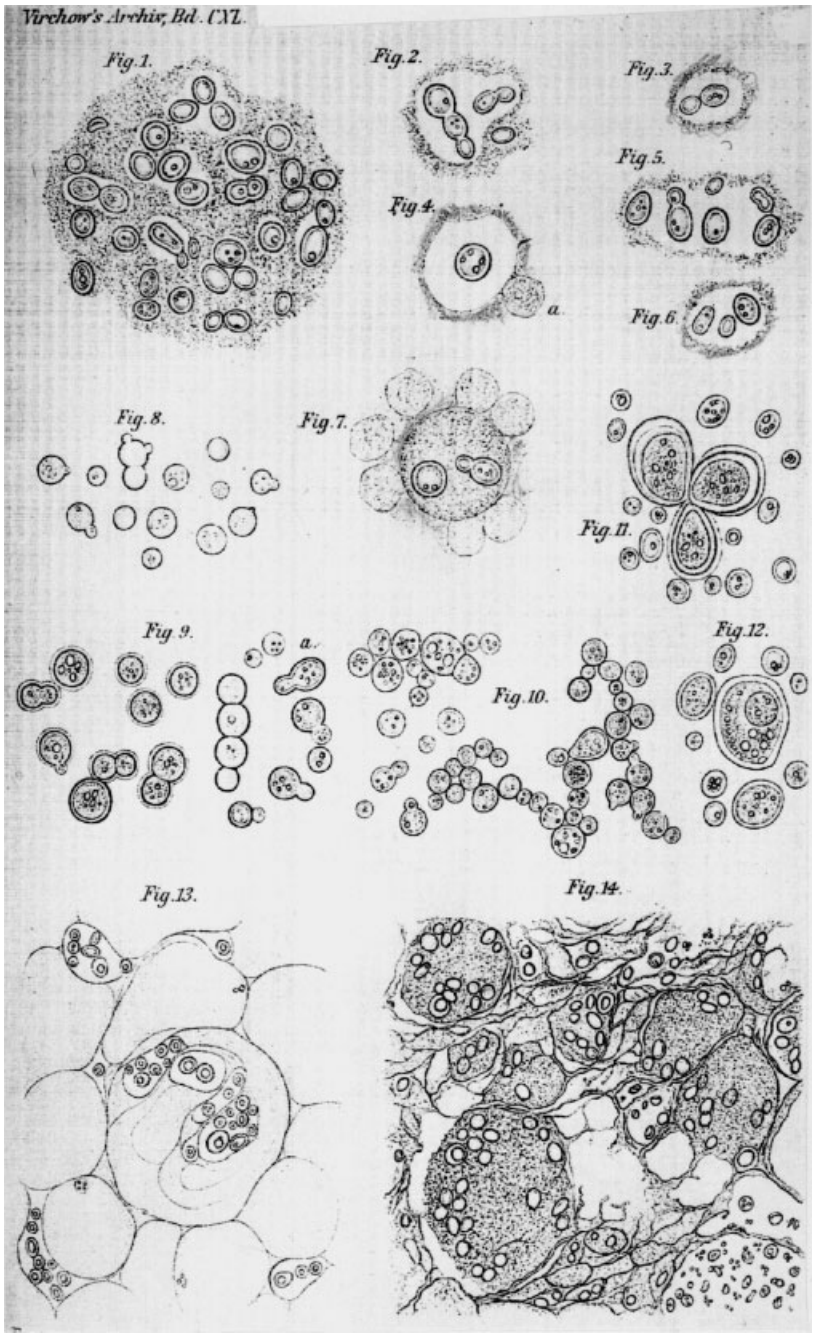

Figure 11 *Busse and Buschke's drawings of capsulated cell of the* Cryptococcus neoformans *(called* Saccharomyces *and the disease saccharomycosis hominis in their publication), showing a moniliform yeast form converted into a 'gelatinous cyst' (Busse 1895).*

Berlin, to new concepts for the identification of the fungus. Staib reported the brown color effect specific for *C. neoformans* produced by nigerseed of the composite *Guizotia abyssinica*. The enzyme responsible for the pigment formed was a phenoloxidase involved in virulence, according to the studies of Kwon-Chung, Polacheck and Rhodes in the 1970s. This work has now been extended with the recognition of melanin as a key virulence determinant.

Another valuable addition to the knowledge about this pathogenic yeast was the discovery of its sexual reproduction by Kwon-Chung (1975), who proposed the genus *Filobasidiella* to accommodate this basidiomycetous yeast species. Kwon-Chung (1976) showed that there are two varieties of *F. neoformans*: *F. neoformans* var. *neoformans*, corresponding to the asexual state *C. neoformans* var. *neoformans*, and *F. neoformans* var. *bacillispora*, corresponding to the asexual state *C. neoformans* var. *gattii.* This last variety was isolated by Gatti (Gatti and Eeckels 1970) in Zaire from an African child with meningitis. It was described as *C. neoformans* var. *gattii* by Vanbreuse-

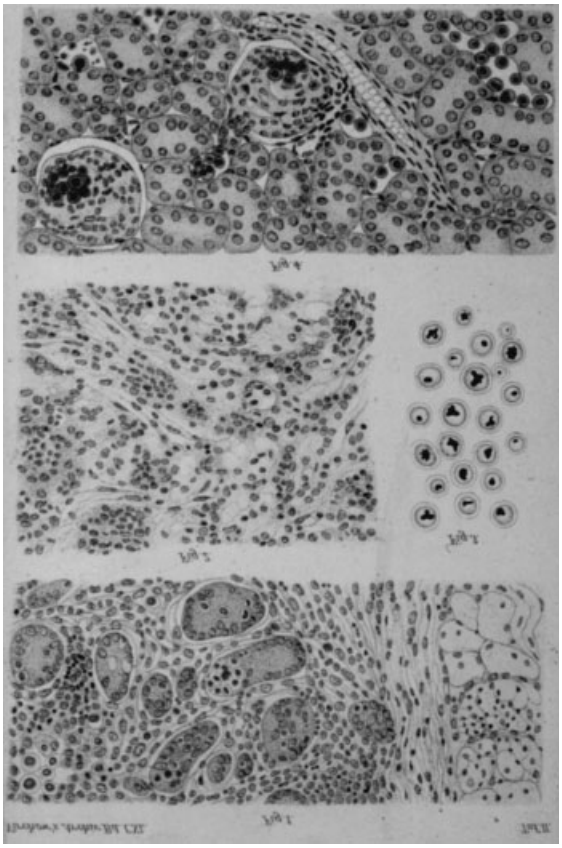

Figure 12 *Histopathological lesions of cryptococcosis with stained yeasts undergoing granulomatous cellular reactions and yeast cells infiltrating the tissue with no cellular reaction. Drawings by Busse (1894).*

ghem and Takashio (1970). Further studies showed that important biochemical, epidemiologic, and pathological differences existed among the four serotypes and the two sexual forms of this basidiomycete fungus (Bennett et al. 1977, 1978; Kwon-Chung et al. 1992, 1994).

In order to evaluate antifungal compounds in a reproducible way, Van Cutsem et al. (1986) established a model in the guinea pig of progressive, disseminated, cryptococcal infections including skin manifestations, as observed in patients with systemic cryptococcosis, particularly in AIDS patients showing a dermotropism of *C. neoformans*.

Another important event in the history of cryptococcosis is that this disease, which was very rare in the past, essentially developed only in people with low host resistance, malignant diseases of the reticuloendothelial system (Hodgkin's disease, lymphoma), or endocrine problems, and was named the 'sleeping giant'by Ajello in 1970. Within a few years cryptococcosis became the 'awakening giant' (Kaufman and Blumer 1978), probably as a result of the intensive immunosuppressive treatments of patients with leukaemia and those undergoing organ transplantations. The incidence in 1978 ranged from 200 to 400 cases of cerebral meningitis per year in the USA, to 15 000 subclinical respiratory infections in New York City alone. A few years after the emergence of AIDS, the frequency and the severity of cryptococcosis increased considerably. In addition, the disease responded poorly to the classic treatment (amphotericin B + 5-fluorocytosine), which necessitated the introduction of new triazole molecules (fluconazole, itraconazole). Cryptococcosis, now a principal life-threatening opportunistic mycosis, was considered to be the 'mycosis of the future' (Drouhet and Dupont 1990). In the USA, among 13 834 AIDS patients, registered by the CDC in October 1985, 904 cases of cryptococcosis (6.5 percent) were diagnosed. In France during the period 1985–88, among 283 diagnosed cases of cryptococcosis, 204 (72.08 percent) had developed in AIDS patients (Drouhet and Dupont 1990) and in 1994 more than 1 300 cases were reported (see also Cryptococcosis).

Aspergillus spp. and aspergillosis

Micheli (1729) described the genus *Aspergillus* and derived its name from the Latin word *aspergillum* (to sprinkle) which referred to the perforated globe used to sprinkle holy water during Catholic religious ceremonies '*aspergus te.*' Link delineated several distinct species in 1809 such as *A. candidus*, *A. flavus*, and *A. glaucus*, which he had isolated from decaying vegetation.

The first reports of infections with *Aspergillus* spp. were those of Mayer and Emmert in 1815, who described an infection in the lung of a European jay (*Garrulus glandarius*), but principally those of the German Fresenius, in 1850, who observed an air sac infection in a captive bird, the Great bustard (*Otis tarda*) at the Frankfurt Zoo. Fresenius named the isolate *Aspergillus fumigatus* and first used the term aspergillosis.

The first cases in humans with detailed microscopic drawings of an *Aspergillus* sp. in vivo were described by Virchow in 1856 (Figure 13). Virchow noted that the organism he had observed (probably *A. fumigatus*) in human disease was closely related to the 'parasitic' vegetable structures growing in living animals reported by Bennett in 1844 and by Sluyter in 1847, except for the association of the pulmonary form with 'pigeon feeder's' disease by Virchow and later, in 1890, by Dieulafoy, Chantemesse, and Widal. In the following years, very few cases of the disease were reported. In 1897, Renon published his thesis showing the association of aspergillosis with certain occupations including pigeon stuffers ('*gaveurs de pigeons*') and wig cleaners. They concluded that moldy grain was the source of the infectious conidia. Renon also showed that some patients had tuberculosis because their primary disease antedated the aspergillosis. Between 1897 and 1938, the aspergillosis mentioned was not the localized fungus ball ('bronch-

Figure 13 *Virchow's drawings of the first case of human pulmonary aspergillosis.* Aspergillus fumigatus *can be recognized from the drawings.*

iectosiant aspergilloma'), which was defined by the French surgeon Devé only in 1938 as a rare colonization of congenital bronchial cysts (see also Aspergillosis).

The growing importance of aspergillosis was recognized only after the remarkable description, by Monod (surgeon), Pesle (physician) and Segretain (mycologist) (Monod et al. 1954), of the development of bronchopulmonary aspergilloma (fungus ball) in the pulmonary cavities of tuberculous patients who had been treated with powerful antituberculous medications. Radiological evidence demonstrated that *Aspergillus* spp., most frequently *A. fumigatus*, colonized preformed cavities in 12 percent of healed tuberculous patients along the radiolucent crest. Aspergilloma is accompanied by the appearance of anti-*A. fumigatus* precipitating antibodies, studied particularly since the 1960s in the UK (Pepys 1969; Longbottom 1986; Longbottom and Austwick 1986), and in France (Biguet et al. 1964; Drouhet et al. 1972). This localized form was observed particularly in Europe (Segretain 1962) where the incidence of tuberculosis was high, but it is now observed worldwide. At the same time, allergic bronchopulmonary aspergillosis was described by Hinson et al. (1952). In addition, progressive invasive aspergillosis in the immunocompromised host has became more and more frequent and severe. Invasive aspergillosis has become a major problem in immunosuppressed or myelosuppressed patients, or recipients of organ transplants. It has raised new, epidemiologic, clinical, immunological, and therapeutic problems. The First International Symposium on *Aspergillus* spp. and aspergillosis (Vanden Bossche et al. 1988) presented a summation of the then current knowledge of this mycosis which has become one of the most important in fungal diseases.

Scedosporium spp. and pseudallescheriasis

The history of the taxonomy of the fungi and of the clinical and epidemiologic aspects of the mycosis, known under various names such as monosporiosis, allescheriosis, petriellidiosis, pseudallescheriasis, or scedosporiosis, is fascinating.

The history of *Monosporium apiospermum,* described in 1911 by the famous Italian taxonomic mycologist Saccardo (1845–1920), started with a white grain mycetoma of the foot of an Italian patient. In 1922, Shear (1865–1956) in Texas (USA) described and named an ascospore-producing fungus isolated from a mycetoma of the foot as *Allescheria boydii*, in honor of the clinician studying this American case. For 30 years, the two fungi were accepted as different agents of mycetoma, until 1944 when Emmons reported that *M. aspiospermum* was the anamorph or asexual state of *A. boydii*. The names of both the teleomorphic and anamorphic states have undergone several successive changes: the genus *Allescheria* was reclassified, in 1970, by Malloch as *Petriellidium*. McGinnis et al., in 1982, recognized the priority of the genus *Pseudallescheria* Negroni et Fisher 1944 and the sexual telemorph became *Pseudallescheria boydii* (Shear) McGinnis, Padhye et Ajello 1972. The anamorph *Monosporium apiospermum* was invalidated by Hughes in 1958 and *Scedosporium apiospermum* (Saccardo) Castellani et Chambers 1919 is now the valid name of the anamorph.

After the first isolation from the soil by Ajello and Zeidberg (1951), numerous studies established its presence as a saprophyte in nature, explaining the source of post-traumatic infections and bronchopneumopathies.

The first clinical infection, other than a mycetoma, was observed by Benham and Georg (1948), who described granulomatous meningitis caused by *P. boydii* in a patient with no underlying disease, after spinal anesthesia a month before the onset of symptoms. The first reported cases of pulmonary infection, resulting from *P. boydii* infections, were those of Creitz and Harris (1955) and Drouhet (1955), followed by numerous reports carefully reviewed by Rippon (1988) and Dupont et al. (1991).

In 1984, Malloch and Salkin described a new species of *Scedosporium, S. inflatum*. The fungus was isolated from a bone biopsy from a 6-year-old boy. Previously, a fungal osteoarthritis of the knee with severe joint destruction, caused by an atypical *S. apiospermum* that was highly virulent for laboratory mice, had later been identified as *S. inflatum* (Drouhet et al. 1991). Since then, more than a dozen cases caused by this species have been described in young boys as a result of trauma to the knee or the foot, in patients who have undergone renal transplantation or in drug abusers (endocarditis and hip arthritis). In 1991, Guého and de Hoog, based on genomic taxonomy (DNA/DNA reassociation, G + C percentage) and the cultural aspects of numerous strains of *Sepedonium* and *Pseudallescheria*, found that *S. inflatum* was identical to *Lomentospora prolificans* Hennebert et Desai 1974, a soil fungus. They proposed the name, *Scedosporium prolificans* (Malloch et Salkin) Guého et de Hoog 1991 (Figure 14).

Mucor spp., Mucorales and zygomycosis (in part)

The nonseptate filamentous fungi with sporangia and sexual reproduction by zygospores, now belonging to the class Zygomycetes and the order Mucorales, were recognized by the first microscopists, namely Hooke (1636–1703), Malpighi (1628–84) and van Leewenhoek (1637–1723). They illustrated these fungi in 1665, 1669 and 1680, respectively, but the genera related to pathogenic fungi were defined and described later as *Mucor* Micheli 1729, *Rhizopus* Corda 1838, *Absidia* van Tieghem 1876, *Rhizomucor* Lucet et Costantin 1899, *Cunninghamella* Matruchot 1903 and, more recently, *Saksenaea* Saksena 1953 and *Apophysomyces* (Misra et al., 1979), which are all new emerging opportunistic pathogens in medical mycology.

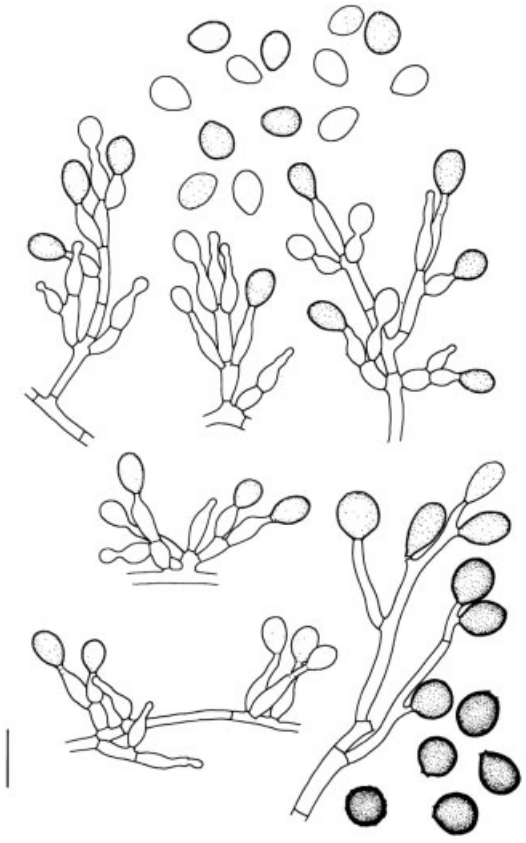

Figure 14 Scedosporium prolificans *(Hennebert and Desai) Guého and de Hoog comb. nov. (1991): a new emerging fungus.*

The earliest reports of authentic zygomycosis were described 150 years ago, but the clinical descriptions were often inaccurate and incomplete as was the identification of the isolates, necessitating accommodation in genera other than those indicated in the old literature. The first authentic human pulmonary case of zygomycosis was recognized by the German Kurchenmeister in 1855, in a cancerous lung. Based on the drawings showing sporangia and nonseptate hyphae, the isolated fungus was called a *Mucor*. After two other doubtful pulmonary cases reported by Fürbinger in 1876, Paltauf published, in 1885 in *Virchow's Arch Pathol Anat*, the first observation of disseminated infection that had started in the larynx and pharynx. The classic primary localizations of rhinocerebral zygomycosis were first observed more than 50 years later (Gregory et al. 1943). Paltauf called the etiologic agent *Mucor corymbifera*, in spite of the absence of cultures for this case. In 1884, Lichtheim isolated from nature two species of *Mucor*, which caused fatal mycoses in rabbits: *Mucor corymbifera* Cohn 1884 and *M. rhizopodiformis* Cohn apud Lichtheim 1884. After a new case of pulmonary mucormycosis described by the Belgian Herla in 1895, Lindt described and found *M. pusillus*, in 1896, as well as *M. racemosus* Fresenius 1850 in animal mycoses.

Since 1943, when Gregory et al. described three cases of rhinocerebral zygomycosis and delineated this syndrome, 40 cases of rhinocerebral zygomycosis are noted per year in the USA. Around 1960, zygomycosis became a progressively increasing mycosis in compromised hosts with ketoacidotic diabetes mellitus (the rhinocerebral severe form) and in immunocompromised hosts; since 1984, the pulmonary form has been observed in 18 percent of patients with malignant leukemias, lymphoma, and severe neutropenia treated with corticosteroids. Gastrointestinal and esophageal zygomycosis is observed in 20 percent of kwashiorkor, malnourished children eating moldy food, and cutaneous or subcutaneous forms in 3 percent of cases from various origins (burns, local trauma, etc.). Zygomycosis became the fourth most common opportunistic mycosis in the compromised host after candidiasis, aspergillosis, and cryptococcosis. Since 1960, organ transplant recipients, particularly recipients of renal transplants who have been treated with stronger and stronger immunosuppres-

sive drugs and who do or do not have associated diabetes, have caused a considerable increase in the number of cases of severe zygomycosis.

Since the 1980s, nosocomial zygomycosis, presenting as primary skin and wound infections caused by *Rhizopus* spp., *Cunninghamella bertholletiae*, *Rhizomucor pusillus*, *Absidia corymbifera*, and now *Saksenaea vasiformis* and *Apophysomyces elegans*, is often reported. Infections have been contracted from contaminated elastic bandages, infected burns, intravenous catheters, surgical wounds, ostomy sites or intravenous drug abuse whether or nor associated with AIDS. Another important condition is desferrioxamine therapy for iron or aluminum overload, which was responsible, between 1986 and 1990, for 24 lethal disseminated cases of zygomycosis caused particularly by *R. arrhizus (oryzae)*, *R. rhizopodiformis*, and *C. bertholletiae*. (For further information on zygomycosis, see also Systemic zygomycosis.)

McGinnis et al. (1993) reviewed 10 cases of rapidly fatal necrotizing fasciitis (Figure 15) caused by *Apophysomyces elegans* after trauma or burns in healthy patients or from various other predisposing conditions.

Figure 15 *Necrotizing fasciitis caused by* Apophysomyces elegans. *Back of patient showing extensive deep débridement in the exposed back muscles and necrotic margins. (From McGinnis et al. 1993)*

Another emerging organism with coenocytic hyphae and asexual spores produced in a sporangium is the oomycete *Pythium insidiosum* (de Cock et al. 1987) (synonyms *P. destruens* Shipton 1987, *Hyphomyces destruens* Bridges et Emmons 1961); this has been responsible for animal diseases and, since 1987, for severe human orbitofacial infections and arteritis among patients in Thailand and the USA with α- or β-thalassemia (Rinaldi et al. 1989). (For further information about *Pythium insidiosum*, see also Pythiosis.)

SYSTEMIC MYCOSES CAUSED BY DIMORPHIC FUNGI

Fungal dimorphism

In medical mycology the term dimorphism has been employed for the pathogenic, highly virulent, dimorphic fungi with a saprophytic, vegetative, mycelial form in nature or under ordinary laboratory conditions, and a pathogenic, unicellular, yeast-like, or spherule form in human and animal tissues. Under this medical definition, three important groups of dimorphic fungi are included, based on their morphology in vivo (see Figure 1).

The first group consists of yeast-like dimorphic fungi (Figures 16 and 17) such as:

- *Histoplasma capsulatum* var. *capsulatum* (dimorphism proven by DeMonbreun 1934) and *H. capsulatum* var. *duboisii*, respective agents of small-form or classic histoplasmosis and African or large-form histoplasmosis
- *Blastomyces dermatitidis*, agent of blastomycosis
- *Paracoccidioides brasiliensis*, agent of paracoccidioidomycosis
- *Sporothrix schenckii*, agent of sporotrichosis.

To this group *Penicillium marneffei* has been added. It is a redoubtable fungus emerging since 1988 in AIDS patients in southeast Asia which has been reviewed (Drouhet 1993a; Drouhet and Dupont 1995). It is the only known species, among more than 200 *Penicillium* spp., that is transformed in tissues into a unicellular form which multiplies not by budding, but by schizogeny. (For further information about *Penicillium marneffei*, see also Penicilliosis).

The second group consists of dimorphic fungi forming spherules in vivo:

- the agent of coccidioidomycosis, *Coccidioides immitis*, was first considered to be a protozoan but proved to be a dimorphic mold only in 1900 (Ophüls and Moffitt 1900) (see also Coccidioidomycosis)
- the agent of rhinosporidiosis thought to be a mycosis by Seeber (1900), but the agent *Rhinosporidium seeberi* has yet to be cultured (see also Rhinosporidiosis).

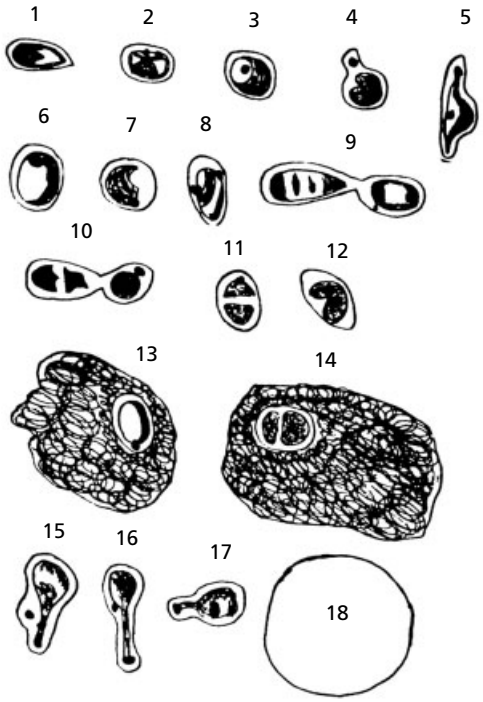

Figure 16 *Darling's drawing of intrahistiocytic aspects of* Histoplasma capsulatum *var* capsulatum *which he considered to be a protozoan, in spite of visible budding yeast cells.*

- the agents of adiaspiromycosis, a rare pulmonary human mycosis, but a frequent pulmonary mycosis in rodents caused by *Emmonsia crescens* and *E. parva* (see also Adiaspiromycosis and other infections caused by *Emmonsia* species).

Besides these pathogenic dimorphic fungi with yeast-like or spherical unicellular forms in vivo, there are other dimorphic or rather polymorphic fungi such as *Candida albicans* with unicellular budding cells and hyphae in tissues or as *Exophiala (Wangiella) dermatitidis*, *Phialophora verrucosa, Fonsecaea pedrosoi*, which are agents of chromoblastomycosis when, in vivo, they form muriform cells. When this parasitic form is absent and subcutaneous, even deep organs such as the brain are invaded by hyphae; the disease is then referred to as a pheohyphomycosis (Ajello 1975b). Their mycological, clinical, and epidemiologic aspects are different from the systemic mycoses caused by the dimorphic fungi.

Pasteur's experimental conditions for M → Y transformation of *Mucor* spp., such as CO_2 high tension, were found for most pathogenic thermal dimorphic fungi for in vitro transformation. The Y form of *Sporothrix schenckii* is obtained at 37°C in a 5 percent CO_2 atmosphere in a simple chemical defined medium with an inorganic $[(NH_4)_2SO_4]$ or organic (arginine) nitrogen source, glucose, biotin (role in CO_2 fixation into the cell)

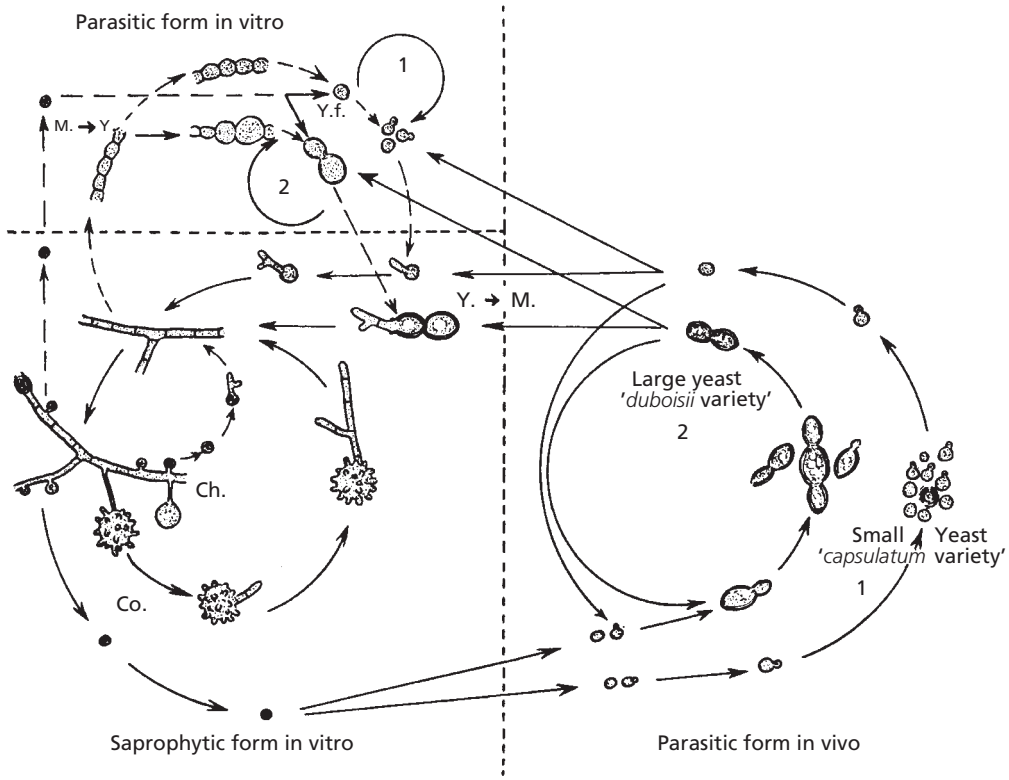

Figure 17 *Diagrammatic representation of the cycle in vitro (saprophytic and parasitic forms) and in vivo of* Histoplasma capsulatum *var* capsulatum *(1) and the* duboisii *var of* H. capsulatum *(2). (Ch., chlamydoconidia; Co. conidium; M.→Y., mycelial–yeast conversion; Y., yeast; Y.f., yeast form; Y.→M., yeast–mycelial conversion.) (Redrawn from Mariat 1964)*

and pyrimidine as growth factors, minerals, and oligoelements (Drouhet and Mariat 1952b). Conant (1941) obtained the difficult transformation of *H. capsulatum* var. *capsulatum* on a complex blood agar medium in sealed paraffinized tubes which provided an increased CO_2 tension. A higher content of CO_2 (15–20 percent) was necessary for *H. capsulatum* var. *farciminosum* on blood agar at pH 7.4 by Bullen (1949). Pine (1954) also found a stimulating effect of CO_2 and, in a more complex, chemically defined, nutritional agar medium in sealed tubes, obtained the transformation and conservation of cultures of the *capsulatum* and *duboisii* varieties of *H. capsulatum* for the production of antisera and vaccines (Pine and Drouhet 1963). Spherule formation in *Coccidioides immitis* is stimulated by 10 percent CO_2 in a synthetic medium.

This category of mycoses includes infections caused by species of *Blastomyces, Coccidioides, Histoplasma*, and *Paracoccidioides*. Their fascinating history began at the turn of the century and is still evolving today.

Histoplasmosis

Histoplasmosis was discovered in 1905 by Darling (1872–1925), an American pathologist and parasitologist working at the Canal Zone Hospital in Panama. There he observed three fatal cases of an intracellular infection of the reticuloendothelial system involving lymphatic tissues and all the principal organs of the body. Darling considered the observed microorganism to be a protozoan and named it *Histoplasma capsulatum* (Figure 16). However, da Rocha-Lima, a Brazilian studying in Hamburg, suggested that *H. capsulatum* was a fungus in 1912–13, because of its similarity to the tissue forms of the agent of epizootic lymphangitis of horses, an intracellular yeast then known as *Cryptococcus farciminosum* (Rivolta 1873) but now known as *H. capsulatum* var. *farciminosum*.

In 1934, DeMonbreun, a pathologist at Vanderbilt University in Nashville, TN, obtained a culture of the etiologic agent of histoplasmosis from a child diagnosed antemortem by Dodd and Tompkins (DeMonbreun 1934). He established the dimorphic nature of the fungus (Figure 17) by studying its in vitro characteristics at 25 and 37°C, and reproduced the disease in experimental animals. Independently, in 1934, Hausman and Schenken also obtained the mycelial form of *H. capsulatum* but erroneously considered it to belong to the genus *Sepedonium*. The culture of *H. capsulatum*, originally grown by DeMonbreun, served as the source of histoplasmin (comparable to coccidioidin from *C. immitis* used by Smith since 1943 to detect coccidioidomycosis), which was used by Christie and Peterson in 1945 in a skin-test survey. They showed that histoplasmosis capsulati was responsible for pulmonary calcifications in infants, young World War II recruits and young control subjects, who were negative for both tuberculin and coccidioidin. Parsons and Zarafonetis reviewed 71 cases of histoplasmosis, in 1945, collected during 1905–45, and found that the disease was rare but uniformly fatal. However, since the work of Christie, Peterson, Palmer, and others, benign asymptomatic histoplasmosis has been considered a widely prevalent disease.

Emmons (1949) first isolated the *capsulatum* variety of *H. capsulatum* from soil around a rodent burrow and under a chicken coop. Positive cultures were obtained only after 156 negative specimens – a feat that demonstrated that perseverance is necessary for successful completion of such a study. Hundreds more isolations from suspected sites and patients in many parts of the world have supplied information of epidemiologic importance. Soil contaminated by the excreta of chickens, pigeons, and bats in the USA, Central and South America, and South Africa, and by the nocturnal fruit-eating oil bird (*Steatornis caripensis*) in caves in Colombia, Peru, Trinidad, and Venezuela, as shown by Ajello and Zeidberg (1951) and Emmons (1958), and air and water, as shown by Furcolow (1958), have proved to be sources of benign pulmonary outbreaks of histoplamosis. The first epidemiologic study on a large scale (since the study in 1945 by Furcolow) led to the rapid development of investigations of all phases of the disease. Since the first complement fixation serological test by Tenenberg for diagnosis in 1947, numerous other tests have been developed for antigen and antibody detection (Wheat et al. 1986). Clinical aspects of histoplasmosis have been described, ranging from pulmonary and splenic calcifications (Schwarz et al. 1955) to the disseminated form, which is now observed in immunosuppressed patients and particularly in AIDS patients (Graybill 1988). Epidemiologic and clinical studies have revealed that histoplasmosis has a worldwide distribution with the densest endemic areas chiefly in the USA, where 40 000 000 people have had the disease and 500 000 new infections occur every year (Rippon 1988). Parallel with these studies, there has been intensive study of the biological aspects of dimorphism (Rippon 1980; Szaniszlo et al. 1983), the regulation of the metabolism of the yeast (Y) and mycelial (M) forms at a molecular level, differences in cell wall composition accompanying morphogenesis (San-Blas and San-Blas 1985, 1993) and the role of temperature for the regulation of the Y′M form (Howard 1967). Another important contribution was the discovery by Kwon-Chung, in 1972, of the sexual state of *H. capsulatum*: *Emmonsiella capsulata* (1972), now known as *Ajellomyces capsulatus* (Kwon-Chung 1972) McGinnis et Katz 1979.

More historical details on this fascinating disease were discussed at two national conferences held in the USA in 1952 and 1962, organized by Furcolow and Ajello, and in books such as *Histoplasmosis* by Sweany in 1960.

A new form of histoplasmosis was discovered as a geographically localized form in central Africa, particularly Senegal, Nigeria, and Zaire. It is characterized by a parasitic tissue-form comprising large, oval yeast cells in giant cells (Figure 17) and by a distinct clinical disease. The cutaneous, subcutaneous and bone lesions predominate over pulmonary and visceral disease. The first case was reported by Catanei and Kervran in 1945 at the Pasteur Institute in Algiers. Other fatal cases were observed by Kervran and Aretas in 1947 and by Duncan, who suggested that the agent was either a species distinct from *H. capsulatum* or a variant (Duncan 1947, 1958). This agent was considered to be a distinct species by Vanbreuseghem in 1952, who named it *H. duboisii* in honor of Dubois, Director of the Institute of Tropical Medicine (Antwerp), where the strain from a Belgian patient infected in Africa was studied (Dubois et al. 1952; Vanbreuseghem 1953). The disease was called African or large-form histoplasmosis, although histoplasmosis is also endemic in Africa. For that reason an alternative term, histoplasmosis duboisii, was proposed (Ajello 1983) to describe the disease caused by *H. capsulatum* var. *duboisii* (Drouhet 1957). Subsequently, this organism was confirmed by Kwon-Chung (1972, 1975) who showed that the sexual states of both varieties are identical. This new form of histoplasmosis, also endemic in Madagascar, now has a small but important place in the pathology of Africa and is an imported mycosis in Europe, particularly in Belgium and France (Drouhet 1989).

More than 200 published cases have been reported among Africans and Europeans, with 30 percent developing severe systemic infections. In animals, the spontaneous infection has been observed only in monkeys imported from Africa into France, England, and the USA. The natural history of this particular form is not well known, but, recently, Guignani et al. (1994) reported the isolation of *H. capsulatum* var. *duboisii* from soil admixed with bat guano from a sandstone bat cave in a rural area of Nigeria.

The third form of histoplasmosis (see also Histoplasmosis), epizootic lymphangitis of horses and mules, was first described by Rivolta (1873), who named the agent *Cryptococcus farciminosum*. This fungus was renamed *H. farciminosum* by Redaelli and Ciferri (1934). It is now considered to be a variety of *H. capsulatum*: *H. capsulatum* var. *farciminosum* (Rivolta) Weeks, Padhye et Ajello 1985, responsible for the disease. It is particularly prevalent among equines in Egypt, India, and Russia.

Blastomycosis

In 1894, Gilchrist observed the first case of a verrucous, granulomatous dermatitis produced by a yeast-like fungus. In 1896, it was named *Blastomyces dermatitidis*, when together with Stokes he published the second case (Gilchrist and Stokes 1896). This disease, once called Gilchrist's disease and the Chicago disease (15 cases were described there in 1901), was considered to be endemic in North America until 1953, when cases were observed in Tunisia (Vermeil et al. 1954), and later in Algeria, Central Africa, Saudi Arabia, India, Israel, Morocco, Mozambique, and South Africa, indicating extensive geographical distribution. The natural habitat of *B. dermatitidis* remains an enigma in spite of various isolates from nature. The discovery by McDonough and Lewis, in 1967, of the sexual state of *B. dermatitidis*, named *Ajellomyces dermatitidis*, is an important event in the history of this disease. (See also Blastomycosis.)

Paracoccidioidomycosis

This Latin American mycosis was first described by Lutz (1908), in a Brazilian patient with severe granulomatous naso-oropharyngeal lesions and cervical adenopathy. Lutz described and cultured this dimorphic fungus which he considered, in tissue, to resemble the parasitic form of coccidioidomycosis, and called the disease a pseudococcidioidal mycosis. The Italian microbiologist, Splendore, described the fungus and its disease in several studies between 1908 and 1912, and Almeida named the fungus *Paracoccidioides brasiliensis* in 1930. Consequently, the disease was called the Lutz–Splendore–Almeida disease. In 1942, Conant and Howell considered this fungus to be similar to *B. dermatitidis* and named it *B. brasiliensis*, and the disease South American blastomycosis. However, later investigators restored the names *P. brasiliensis* and paracoccidioidomycosis (Figure 18). The ecology of *P. brasiliensis* remains an unsolved puzzle (Restrepo 1985), but the disease responds well to azole antifungals (Restrepo 1990). (See also Paracoccidioidomycosis.)

Coccidioidomycosis

Now recognized as a disease of major public health importance in the USA and especially Mexico, coccidioidomycosis was first described, in 1892, by Posadas in Argentina. Posadas was a student of the famous pathologist Wernicke. He considered this granulomatous disease to be a neoplasia. Two years later, Rixford and Gilchrist (1896) observed a new case in California, considered that the agent was a protozoan, and named it *Coccidioides immitis*. It was later identified by Ophüls and Moffitt (1900) as a fungus with a dimorphic life cycle (Figure 19). The dimorphism of *C. immitis* was critically studied and reviewed by Cole et al. (1993). The disease is considered to be rare in Argentina (only a few cases in 1929, 27 in 1967); however, it is most common in southern California. In 1915, Dickson of Stanford University reported 40 cases of a primary pulmonary infection with mild and

fatal disseminated evolution. In 1932, Stewart and Meyer isolated *C. immitis* from soil; in 1942 Emmons isolated it from soil as well as from rodents, and as a result of the extensive studies of Dickson, Gifford, and Smith, it was established that San Joaquin Valley fever was coccidioidomycosis. The work of C.E. Smith (1904–67) on the epidemiology, diagnosis, and prophylaxis of coccidioidomycosis was considerable and has been the subject of a voluminous literature. The work of Smith, Huppert, Cole, Pappagianis, Levine, and others contributed largely to the understanding of the immunology of this disease. Ajello edited the proceedings of the second symposium on coccidioidomycosis in 1967, and of the third symposium in 1977, followed by the fourth symposium in 1984 and several books (Fiese 1958; Ajello 1977). (See also Coccidioidomycosis.)

Emmonsia spp. and adiaspiromycosis

Studying the ecology and natural history of *C. immitis* in the desert of southern Arizona, Emmons and Ashburn (1942) revealed that many rodents had mycotic pulmonary lesions and described the mycelial fungus obtained in culture as *Haplosporangium parvum* because of its resemblance to the phycomycete *H. bisporale*. Emmons described the adiaspores in the tissues and the later work showed that the conidia of the new filamentous fungus grew in vivo to form uninucleate spherules (< 40 mm), with thick laminated walls and no endospores. this cystic pulmonary disease had been described earlier by Kirschenblatt in 1939. He had observed adiaspores in the lungs of rats from Transcaucasia (Russia), and named the organism *Rhinosporidium pulmonale.* The organism was not isolated and was therefore not given a Latin name. In 1947, Dowding reported a fungus similar in culture to *H. parvum*, but with adiaspores attaining a diameter of 270 mm in rodent lungs from western Canada and the northern USA. Jellison, in numerous publications between 1950 and 1959, reported the widespread distribution of this mycosis in rodent lungs and other small mammals in Africa, Ecuador, Finland, Japan, Korea, Norway, Sweden, the USA, and Yugoslavia, in animals preserved in formalin since 1845, and in France, in certain specimens of animals preserved for 60 years in the Museum of Natural History of Paris (Jellison et al. 1961; Jellison 1969).

The natural habitat of the *Emmonsia (Haplosporangium)* spp. is soil. In 1954, Menges and Haberman reported the isolation of *H. parvum* from soil in Missouri, but Emmons found the strain to be different from isolates of this species. In 1959, Ciferri and Montemartini isolated *E. parva* from soil in Italy. They renamed this fungus and placed it in the new genus *Emmonsia*. In 1960, Emmons and Jellison, after studying several hundred dimorphic fungi in cultures and in pulmonary tissues of naturally, or experimentally, infected animals, described a new species *E. crescens* which could be segregated from *E. parva* on the basis of its larger adiaspores, which also enlarge without multiplication in host tissue. Since the first human case of pulmonary adiaspiromycosis described in France by Doby-Dubois (1964), numerous other chronic benign pulmonary cases have been reported in Brazil, Czechoslovakia, France, India, Russia, and Venezuela. All these cases were caused by *E. crescens*, except for a case in 1993 in an AIDS patient observed in Colombia which was caused by *E. parva* (Echavarria et al. 1993). (See also Adiaspiromycosis and other infections caused by *Emmonsia* species.)

Infection caused by *Penicillium marneffei* – the new emerging systemic mycosis in AIDS

Penicillium marneffei (Capponi et al. 1956; Segretain 1959), the only dimorphic pathogenic *Penicillium* sp. among 223 described species of *Penicillium*, was first isolated from bamboo rats (*Rhizomys sinensis*), native to Burma, China, and Vietnam (Capponi et al. 1956). These rats had been kept in captivity for experimental infections at the Pasteur Institute of Indochina at Dalat, and they developed a fatal reticuloendothelial mycosis. The fungus isolated from a rat was used to infect a laboratory mouse and both fungus and mouse were sent to the Pasteur Institute in Paris to be studied. The fungus was identified by Segretain as a new species, *P. marneffei*, in honor of Marneffe, Director of the Pasteur Institute of Indochina.

The typical feature of this pathogenic fungus is its thermal dimorphism: unicellular, oval or elongated cells, which multiply by schizogeny in vivo in histiocytes and macrophages or in vitro at 37°C. At 25°C, *P. marneffei* grows as a mold with hyphae and conidia, producing a characteristic diffusible red pigment.

Segretain (1959) pricked his finger accidentally, during experimental studies, with a needle used to inoculate hamsters with *P. marneffei*. He developed a small nodule at the site of inoculation 9 days later, followed by lymphangitis and axillary lymph node hypertrophy. Antifungal sensitivity studies by Drouhet (in Segretain 1959) demonstrated high in vitro sensitivity of this fungus to nystatin. An intensive treatment with oral nystatin (20 million units – 10–13 times the usual daily dose) for 30 days cleared the infection. This accidental infection emphasized the possibility of human pathogenicity.

The first natural human infection was described only 17 years later by DiSalvo et al. (1973) in the USA, in a 64-year-old minister who had traveled in southeast Asia. *P. marneffei* infection was diagnosed when the patient underwent a splenectomy for management of Hodgkin's disease. A second imported pulmonary case was reported in the USA by Pautler et al. (1984), in a

59-year-old man who had travelled extensively in the Far East.

Since 1984, cases of *Penicillium* infection have been reported in southern China by Deng and Connor in 1985, and in Thailand by Jaynetra et al. in 1984, among healthy or immunocompromised patients, as a systemic mycosis involving the entire reticuloendothelial system, and mimicking histoplasmosis. Since 1988, numerous cases have been reported among AIDS patients from Australia, France, Italy, the Netherlands, the UK, and the USA, who had travelled in southeast Asia, and in an African patient diagnosed in France who had acquired a laboratory infection in Paris. The clinical, epidemiologic, mycological and biological aspects of 44 cases in patients negative for the human immunodeficiency virus (HIV) and 44 cases in HIV-positive patients were analysed and compared (Drouhet 1993a). In the following 2 years an increasing number of AIDS patients from Thailand and Hong Kong (Supparatpinyo et al. 1994) have been infected with *P. marneffei*. The number of cases reported is now close to 400 (Drouhet and Dupont 1995).

Epidemiologic studies since 1986 have shown that wild bamboo rats in China, Thailand and Vietnam – *Cannomys badius*, *R. pruinosus*, *R. sinensis*, and *R. sumatrensis* – are commonly infected by *P. marneffei* (Deng et al. 1988; Ajello et al. 1995). Penicilliosis can be considered to be a 'new emerging systemic mycosis' for individuals with HIV infection living or traveling in southeast Asia. This constitutes a dangerous risk for contracting penicilliosis. This disease must be included in the clinical definition of AIDS as other systemic mycoses already are (candidiasis, coccidioidomycosis, cryptococcosis, and histoplasmosis) in defined endemic areas (Drouhet 1993a). (See also Penicilliosis.)

SUBCUTANEOUS MYCOSES AND OTHER DEEP MYCOSES

Mycetoma

The term mycetoma encompasses all pseudotumors produced by fungi. It was first used by Vandyke Carter in 1874 after he had established the fungal etiology of this disease. The division of this disease into separate categories dependent on a fungal or actinomycotic etiology was first suggested by Pinoy (1913). At present, according to the literature, including comprehensive and extensive reviews by Mariat et al. (1977), who surveyed 854 cases identified between 1940 and 1960, and the classic manuals of medical mycology by Emmons et al. (1977) and Rippon (1988), the single clinical entity mycetoma may be evoked by 33 well-recognized agents, 23 species of true fungi (i.e. eukaryotic microorganisms) and 10 actinomycetes (i.e. prokaryotic organisms). These figures, as well as the number of cases, have increased according to the last review of Kwon-Chung and Bennett (1992).

Many authors from all over the world have studied this disease. In particular several groups of medical mycologists have contributed: Abbott in 1956 in clinical studies of 1 231 Sudanese mycetomas, Murray on the immunology of mycetoma, Hay and Mackenzie on ultrastructure and histopathology, Mahgoub in 1976 in Sudan (epidemiology, immunology, and therapy of mycetoma), Latapi and Lavalle in Mexico, Mackinnon in Uruguay, Borelli in Venezuela, da Silva Lacaz in Brazil (da Silva Lacaz 1983), Ajello, Conant, Emmons, Gordon, and Rippon in the USA, Avram et al. in Romania, Vanbreuseghem in Belgium, and many others. In France, the first historical studies on actinomycotic and fungal agents of mycetoma by Vincent in 1894, Brumpt in 1906, Laveran in 1906, Pinoy in 1913, and Langeron in 1928, have been developed intensively at the Pasteur Institute since 1956 by Segretain and Mariat, in association with the histopathologists Destombes, Camain, and Ravisse; there was also help from French and African physicians, surgeons, and hygienists. All these data have been reviewed (Mariat et al. 1977). Several discoveries have helped to clarify the extremely confusing host–parasite relationship of this syndrome with its 23 fungal agents. In addition to the discovery of new agents of mycetoma (Figure 20), i.e. *Leptosphaeria senegalensis* (Segretain et al. 1959), *Leptosphaeria tompkinsii* (Segretain et al. 1974), *Neotestudina rosatii* (Segretain and Destombes 1961), there have been new data on the epidemiology of mycetomas, such as the discovery by Segretain of these two fungi in African soil and on the thorns of acacia trees, the discovery of the sulfurophilic fungus *Madurella mycetomatis* in termitaria (Segretain and Destombes 1969), the classification of mycetomas according to the microscopic aspects of actinomycotic and fungal 'grains' in tissues (Figure 20). There are many questions to be answered and work to be done on the eumycetomas, particularly on their treatment which is ineffective in most cases, and which necessitates amputation of legs and feet. Two International Symposia (Venezuela 1977; Mexico 1987) have been dedicated to the mycetomas. (See also Eumycetomas.)

Pheohyphomycoses

As of 1994, 101 species of pheoid fungi had been isolated from human and animal infections and grouped by Ajello (1975b) under the umbrella term pheohyphomycoses. Taxonomically, the fungi responsible for pheohyphomycosis include hyphomycetes in the Dematiaceae, Spheropsidales and various Ascomycetes. Clinically, there is a wide spectrum of infections which vary from superficial colonization of the skin and hair or the cornea of the eye, to cyst formation, to cutaneous, subcutaneous, cerebral, and systemic opportunistic infec-

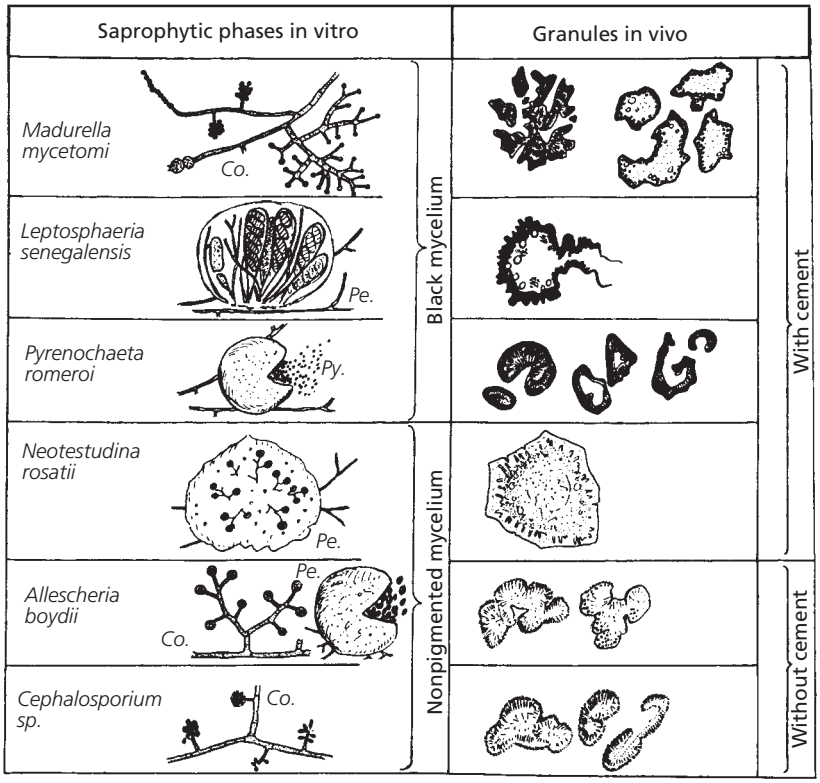

Figure 20 *Diagrammatic representation of the principal agents of fungal mycetomas in vitro and in vivo (Co., conidium; Pe., perithecium; Py., pycnidium). (Redrawn from Mariat 1964)*

tions; these have all been well detailed by Ajello (1975b, 1981); McGinnis (1983); Rippon (1988); and Matsumoto et al. (1994). (See also Adiospiromycosis and other infections caused by *Emmonsia* species.)

Sporotrichosis

As pointed out by Mariat (1968), sporotrichosis can be considered a historical 'model of medical mycology.' The first case of sporotrichosis was reported by Schenck, from the Johns Hopkins Hospital in Baltimore in 1898. The fungus was isolated by Schenck and classified in the genus *Sporotrichum* by the plant mycologist E.F. Smith. The second case, also reported from the USA (Chicago) by Hektoen and Perkins in 1900, was observed in a boy who had struck his finger with a hammer. He developed an inoculation chancre with lymphocutaneous lesions. The authors named the fungus *Sporothrix schenckii*. It is a dimorphic fungus (Figure 21) with a yeast form obtained in a chemically defined medium under 5 percent carbon dioxide (Drouhet and Mariat 1952b). The lesions cured spontaneously and 65 years later the patient still had a positive sporotrichin skin test. In Europe, the disease was initially described in 1903 by de Beurmann and Ramond. The fungus isolated was studied in 1910 by the French botanist, Matruchot, who considered it to be a species different from *S. schenckii* because of the presence of a black pigment. It was named *Sporotrichum beurmannii*. The identity of the American and French species was established in 1921 by Davis and, in 1962, Carmichael determined that *Sporothrix schenckii* is the correct binomial for the fungus. Between 1906 and 1912, de Beurmann and Gougerot identified at least 10 more cases and tabulated more than 200 additional cases in their famous book, *Les sporotrichoses* (de Beurmann and Gougerot 1912). They were the first to suggest that sporotrichosis could be considered as an opportunistic infection, which has recently been confirmed by the occurrence of sporotrichosis in AIDS. Following the suggestion of Sabouraud, in 1903 de Beurmann and Ramond were the first to employ iodides in the chemotherapy of sporotrichosis with remarkable success (de Beurmann and Gougerot 1912). This therapy still remains the treatment of choice for sporotrichosis. Over a period of 50 years, potassium iodide remains the only oral chemotherapeutic agent for deep mycoses. To date several hundred cases have been reported all over the world, particularly in Europe. Curiously, since 1940, sporotrichosis has virtually disappeared from Europe. (See also Sporotrichosis.)

Intensive studies on the ecology and epidemiology of sporotrichosis, reviewed by Mariat (1968) and Rippon (1988), established that *S. schenckii* can be isolated from soil, timber, house plants, straw, bird nests, and animal burrows, etc. The most endemic areas are Latin America

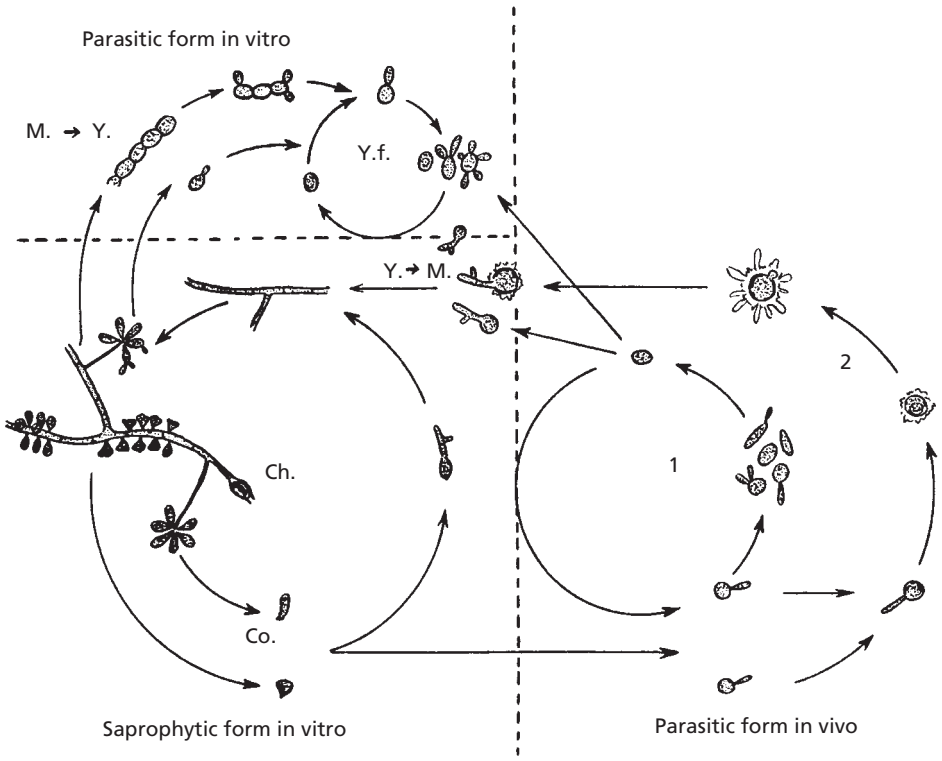

Figure 21 *Diagrammatic representation of the cycle of* Sporothrix schenckii *in vitro (mycelial and yeast forms) and in vivo (Ch., chlamydoconidium; Co., conidium; M.→Y., mycelial–yeast conversion; Y.f., yeast form; Y.→M., yeast–mycelial conversion; 1, 'cigar bodies;' 2, asteroid bodies). (From Mariat 1964)*

and South Africa. *S. schenckii* is phylogenetically related to the plant fungus *Ceratocystis stenoceras* (Mariat 1977).

Chromoblastomycosis and its agents

The term chromoblastomycosis was coined by the Brazilian mycologists and dermatologists Terra, Torres, Fonseca, and Area Leao in 1922, to define a clinical entity presenting with verrucous dermatitis caused by various pheoid fungi. The attempt by Moore and Almeida, in 1935, to replace the term chromoblastomycosis with chromomycosis, including cases of similarly pigmented hyphal fungi, was disputed by Ajello (1974) in favor of the term pheohyphomycosis for cutaneous, subcutaneous, cerebral, and systemic opportunistic infections, caused by a larger spectrum of pheoid fungi. Historically, although chromoblastomycosis is essentially a tropical and subtropical disease, the first authentic case was reported in a patient from Boston (USA) by Lane and Medlar in 1915. The fungus was named *Phialophora verrucosa* Medlar 1915. Pedroso and Gomes (1920) reported four cases from Brazil of the disease called locally 'formiguiero.' One of the patients had been observed since 1911 and is considered to be the first known case of chromoblastomycosis. The etiologic agent was considered to be different from *P. verrucosa* and was named *Hormodendron pedrosoi* by Brumpt in 1920. The valid name is *Fonsecaea pedrosoi* (Brumpt) Negroni 1936. This species is the most frequent agent of chromoblastomycosis in Latin America. The first case outside the Americas was described in 1927 by Montpellier and Catanei from the Pasteur Institute of Algiers. The responsible fungus was described as *Hormodendron algeriensis* (now *Fonsecaea pedrosoi*). In Madagascar, Brygoo and Segretain (1960), during the 4-year period 1955–59, reported a high prevalence of 129 cases (a case rate of one per 32 500 population). Numerous other cases were found in Central and South America, Africa, Asia, and Australia, where intensive mycological studies were performed for identification and taxonomic classification of the dimorphic agents (Figure 22) of chromoblastomycosis. (See also Chromoblastomycosis.)

Five principal agents of chromoblastomycosis have been recognized since 1915:

1. *Phialophora verrucosa* Medlar 1915
2. *Fonsecaea pedrosoi* (Brumpt) Negroni 1936
3. *Fonsecaea compacta* Carrion 1940
4. *Cladophialophora carrionii* Trejos 1954, genetically related to *P. verrucosa* and *F. pedrosoi*
5. *Rhinocladiella aquaspersa* (Borelli) Schnell, McGinnis et Borelli (1983).

Among numerous historical, mycological, and epidemiologic studies on chromoblastomycosis and its responsible fungi, special mention is necessary for the

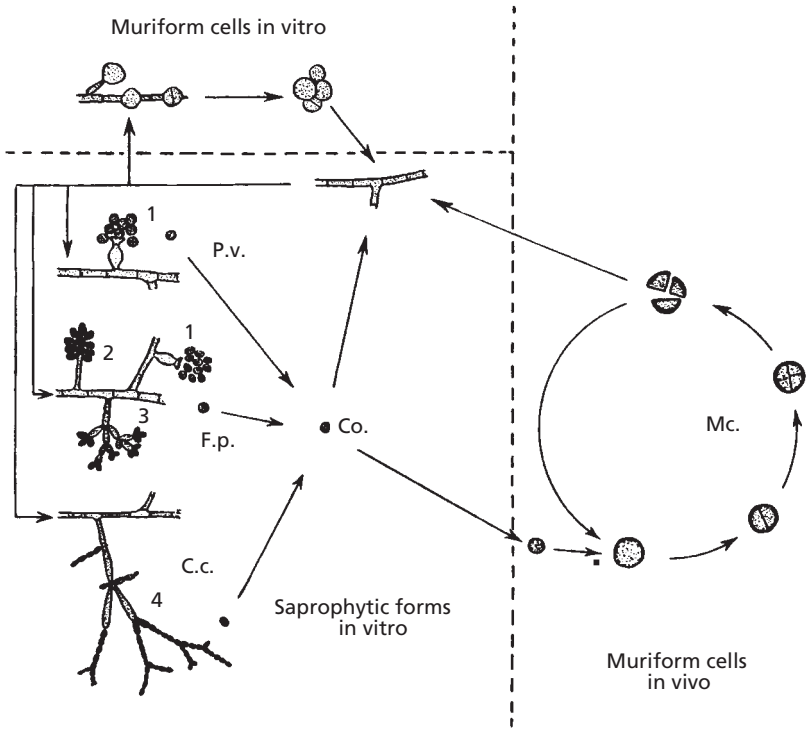

Figure 22 *Diagrammatic representation of the cycles of three agents of chromoblastomycosis in vitro (saprophytic and tissue forms) and in vivo (C.c.,* Cladophialophora carrionii*; Co., conidium; F.p.,* Fonsecae pedrosoi*; Mc., muriform cells; P.v.,* Phialophora verrucosa*; 1, phialide form; 2, acrotheca form; 3, short cladosporium form; 4, long cladosporium form). (Redrawn from Mariat 1964)*

studies of Carrion between 1935 and 1971 and Silva between 1947 and 1971 at the School of Tropical Medicine, San Juan, Puerto Rico and Columbia University, New York, where new species were identified and the parasitic form obtained in vitro. The first evidence that the etiologic agents exist in nature was obtained by Conant (1937b) at Duke University (Durham, NC). He demonstrated that *P. verrucosa* was a cause of 'blueing' of lumber, followed by the discovery of the presence of *F. pedrosoi* and *C. carrionii* in timber, soil, wood or pulps, and air, and in numerous infections in animals with characteristic muriform cells in tissues. The first immunological studies in chromoblastomycosis were performed by Conant and Martin (1937). More recently, in Venezuela, Zeppenfeldt et al. (1994) isolated *C. carrionii* from the medullary tissue of two members of the family *Cactaceae* with 'muriform cells' similar to those in patients with chromoblastomycosis.

HISTORICAL DEVELOPMENTS IN MEDICAL MYCOLOGY

The International Society for Human and Animal Mycology

Medical mycology was recognized as an individual full branch of microbiology only in 1954 with the creation of the International Society for Human and Animal Mycology (ISHAM), at the Thirteenth International Botanical Congress in Paris. Until that time, sessions on the mycoses were admitted (sometimes with difficulty) at dermatological and botanical congresses. The idea had long been encouraged by some mycopathologists, such as those participating in the Fifth Congress on Microbiology in Rio de Janeiro (1950), but nothing was decided until the Sixth International Congress on Microbiology in Rome in 1953, when Redaelli and Ciferri invited a small group of mycologists composed of Vanbreuseghem (Belgium), Ainsworth (the UK), Segretain, Drouhet, Mariat (France), Lodder (the Netherlands), Seeliger (Germany), Paldrok (Sweden), and several others to found the International Society for Human and Animal Mycology (ISHAM), which was formalized in 1954, in Paris. A president was elected (Redaelli, Milan), as well as a very active general secretary (Vanbreuseghem, Anvers) and four vice-presidents: Segretain (Paris), Emmons (Bethesda), Ainsworth (Exeter), and Negroni (Buenos Aires). Mycologists from a host of other countries have joined ISHAM, which, as a result of the value of scientific contributions from its members, has encouraged the steady development of medical mycology as an individual branch of medical microbiology, alongside bacteriology, parasitology, and virology.

Once ISHAM was established, some founders and charter members claimed the right to form National Societies of Medical Mycology for intensive education,

training, and development of research in this field in their own countries. Foundation of the Société Française de Mycologie Médicale in 1956 was followed by the Japanese Society for Medical Mycology (in 1957), the Deutschsprachige Mykologische Gesellschaft (in 1960), the British Society for Mycopathology (in 1961), the Société Belge de Mycologie Humaine et Animale, the Medical Society of the Americas (in 1961) and another 18 other national societies all affiliated to ISHAM. The ISHAM congresses to date have been held in Paris (1954), Lisbon (1958), Montréal (1962), New Orleans (1967), Paris (1971), Tokyo (1975), Tel Aviv (1979), Palmerston (1982), Atlanta (1985), Barcelona (1988), Montréal (1991), Adelaide (1994), Salsomaggiore, Italy (1997), Buenos Aires (2000), and San Antonio (2003).

International and National Societies have contributed through their symposia, workshops, reference committees, and publications to the development of basic and applied research, education, and training. Their historical evolution is recorded in several publications (Ainsworth 1986; Drouhet 1991; Espinel-Ingroff 1996).

Literature on medical mycology

The literature of medical and veterinary mycology directed towards teaching and research has increased considerably since 1945, at a rate estimated to be about equal to that of scientific literature in general. The *Review of Medical and Veterinary Mycology* (*RMVM*), the quarterly journal of abstracts published by the Commonwealth Mycological Institute, presents complete information on this literature. In 1966, Ainsworth, analyzing the pattern of the medical and veterinary literature reviewed since the foundation in 1943 of the *RMVM*, estimated that the increase in the number of abstracted papers was linear and had doubled over a 12-year period. Since these data, the increasing number of papers published concern principally the immunology and chemotherapy of the mycoses. The presidential address of Mackenzie (1992) at the Eleventh Congress of ISHAM held in Montréal (Canada) gave a full analysis of the evolution over the last five decades, with topics of interest ranging from laboratory studies largely directed at fungal biology (the 1960s), pathology, etiology/epidemiology (up to the 1970s) to antifungal/chemotherapy (dominant since the 1980s), immunology, host–parasite relations, and, more recently, molecular biology.

Several publications are devoted exclusively, or in large part, to medical mycology:

- The *Journal of Medical and Veterinary Mycology* (*JMVM*), formerly named *Sabouraudia*, in 1961, when this journal was founded as the official journal of ISHAM. The four annual numbers of *Sabouraudia* were increased to six in 1985 when the journal changed its name to *JMVM* with nearly 150 papers annually. Two large volumes were published of the Proceedings of the last Congresses of ISHAM (Montréal, 1992; Adelaide, 1994) [*J Med Vet Mycol* 1992, **30** (Suppl 1): 1–331; *J Med Vet Mycol* 1994, **32** (Suppl 1): 1–420].
- *Mycopathologia*, founded in 1938 by Ciferri and Redaelli under the name *Mycopathologia et Mycopathologia Applicata*, one of the oldest journals of mycology, devoted to the fungi of plant pathology, mycotoxicoses, applied industrial mycology, and human and animal mycoses.
- *Mycoses*, a bimonthly journal since 1988, formerly named *Mykosen*, official publication of the German-speaking Mycological Society.
- The *Journal de Mycologie Médicale (Journal of Medical Mycology)*, founded in 1991 (formerly, since 1956, the *Bulletin de la Société Française de Mycologie Médicale*), an international journal (in English and French) for mycological studies related exclusively to human and animal mycology.
- The *Japanese Journal of Medical Mycology*, founded in 1956.

Besides these publications devoted to medical mycology, there are other general medical journals that publish, only occasionally, articles on various aspects of human mycoses, such as *Journal of Infectious Diseases, Reviews of Infectious Diseases, Infection and Immunity, Clinical Infectious Diseases, American Journal of Medicine,* etc., or about fungi of medical interest, such as *Antonie van Leewenhoek, Mycotaxon, Experimental Mycology*, and national or regional journals of some Societies of Medical Mycology.

During the period up to World War I (1914), the representative mycopathological textbooks and monographs included those on dermatophytes, such as Morris's *Ringworm in the light of recent research* (London), published in 1898, although the main texts were the monumental book of Sabouraud, *Les teignes,* published in 1910, and the book on sporotrichoses by de Beurmann and Gougerot (1912). Robin's *The vegetals* (1853), in which the mycoses in human and lower animals are developed, and two French monographs on aspergillosis by the veterinarian Lucet and the medical pathologist Renon, published in 1897, complete this pioneering period. The truly educational period for mycopathologists began with the famous *Manual of tropical medicine* (first published in 1910; subsequent editions in 1913 and 1919) by Castellani, considered to be one of the first modern medical mycologists, and Chalmers, and the *Précis de parasitologie* by Brumpt (first edition in 1910, sixth edition in 1949). These handbooks were followed by Dodge's *Medical mycology* (1935), an extensively referenced book with 900 pages and 4 000 references. The breakthrough in medical mycology teaching occurred in 1944, when Conant and his colleagues Martin, Smith, Baker, and

Callaway at Duke University, Durham, NC, published the *Manual of medical mycology* (Conant et al., 1944, 1954, 1971). This book set the pattern for subsequent textbooks such as those of Emmons, Kwon-Chung, and Rippon, the latter from the Pritzker School of Medicine, University of Chicago, entitled *Medical mycology*. From the first edition of 1974 to the third edition of 1988, this book gave the most significant changes occurring in recent years, but it also gives historical data for all pathogenic fungi and actinomycetes. This book still represents a powerful tool which will inspire researchers and clinicians for many years to come.

Other general textbooks, manuals, monographs and proceedings (such as Langeron 1945, 1952; Nickerson 1947; Lodder and Kreger-van Rij 1952; Littman and Zimmerman 1956; Baker 1971; McGinnis 1980; Howard 1983; Rose and Harrison 1987; etc.) have been published and the reader can also refer to Ainsworth (1986) and Drouhet (1991).

Education in medical mycology

In medicine and health sciences, medical mycological education was carried out with minimal mycological input at the start; but, progressively, postgraduate courses have been developed by well-trained mycologists. The training of mycopathologists and education in medical mycology started in the second half of the nineteenth century in Europe (mainly in France, Great Britain, Italy, Germany, Belgium, the Netherlands), North America (the USA, Canada), Latin America (Argentina, Brazil, Uruguay, Colombia, Venezuela, Mexico) and in the second half of the twentieth century in Asia, Africa, and Australia. This evolution has largely been described and analyzed for all countries by Ainsworth (1986); Drouhet (1991) and more recently for the USA by Espinel-Ingroff (1996). Ajello (1975a) pointed out that the history of medical mycology can well be divided into the periods BC and AC – before Conant and after Conant. He cited the work of Bill Conant and his colleagues at Duke University as a milestone in ending the previous perfunctory treatment of medical mycology which had prevailed before his era.

Another important course on medical mycology was initiated in 1947 by Ajello, Director of the Division of Mycotic Diseases at the Centers for Disease Control in Atlanta, Georgia. This month-long course was directed primarily at staff members of state and city health departments and federal agencies, and later also to international institutions (Ajello et al. 1975). In addition to the 4-week course with Georg, Kaplan, Padhye, Kaufman, Standard, and Ajello, courses in veterinary and medical mycology, mycoserology, exoantigen procedures for pathogenic fungi, and public health mycology were organized.

Other federal mycological laboratories, including the National Institutes of Health (Bethesda, MD), where Emmons (1900–85) was appointed in 1936, contributed to the development of modern medical mycology. Emmons' book, *Medical mycology* (Emmons et al. 1963, 1970, 1977), followed by that of Kwon-Chung and Bennett (1992), contributed significantly to the education of mycopathologists. A great number of other medical mycological courses are now available in the USA, Salkin (1988). Twenty-four universities or colleges in the USA provide graduate research programs in medical mycology leading to a doctoral degree.

In the UK, since the end of the nineteenth century, research in medical mycology was dominated by interest in the dermatophytes (Fox 1863; Adamson 1895). New developments were realized after World War II. Duncan (1884–1958), at the London School of Hygiene and Tropical Medicine, was the first Reader in Medical Mycology at London University. Ainsworth, who was interested in medical and veterinary mycology, was one of the founding members of ISHAM (1953–54). He contributed to the creation of the Medical Mycology Committee of the Medical Research Council (1943–69) and developed, with the late Phyllis Stockdale, the *Review of Medical and Veterinary Mycology* (*RMVM*), a joint publication of the Bureau of Hygiene and Tropical Medicine, the Imperial Bureau of Animal Health at Weybridge, and the Imperial Mycological Institute. Important centers for medical mycology at Leeds, Glasgow, and Bristol were developed. A history of important developments in medical mycology in the UK was outlined by Ainsworth, who was author of numerous books dedicated to fungi and to the history of medical and veterinary medicine (1986), general mycology (1976) and animal mycoses (Ainsworth and Austwick 1973). Consequently, Ainsworth made a substantial contribution to bettering knowledge of this branch of microbiology. At the Commonwealth Mycological Institute, Kew, Stockdale rediscovered the sexual state of *Microsporum gypseum*, a starting point for significant further research in this field. In 1958 at Glasgow University, Gentles discovered the oral activity of griseofulvin on tinea. Stockdale, editor of the *RMVM* for many years, and Gentles, Odds and Evans, editors of *Sabouraudia* (later *JMVM*), contributed a great deal to education in medical mycology. A Mycological Diagnostic Laboratory was set up in 1959 in the Department of Microbiology, Queens University, Belfast.

In France, Sabouraud (1864–1938), trained at the Pasteur Institute under Roux (1891) and at the Saint Louis Hospital, the center of French dermatology at that time, was the father of modern medical mycology even though he did not do much university teaching. His 'Laboratoire des Teignes' became a shrine for dermatologists and mycopathologists from all over the world. The first regular university course on medical mycology was organized, at the Faculty of Medicine in Paris, by

Langeron (1874–1950); it took place in the Department of Parasitology and was directed by Brumpt (1877–1951), who had been interested over many years in the human mycoses (particularly mycetomas and black piedra). Numerous French and other distinguished mycologists such as Talice (Uruguay), Negroni (Argentina), Ota (Japan), and Milochevitch (Yugoslavia), followed his teaching that was devoted, particularly, to yeasts and dermatophytes. In 1887, Pasteur (1822–95), at the end of his long career as father of modern microbiology, founded the Institute that bears his name, independent of university and state institutions. He assigned Roux to organize a course for the study of all microorganisms responsible for infections in humans and animals, which became the well-known annual Great Course of the Pasteur Institute. Each microorganism was treated by a specialized microbiologist. The pathogenic fungi of humans and animals were well covered in this course. Four lectures were given by Magrou (1883–1951), botanist and physician, head of the Department of Mycology and Plant Physiology (created by Pinoy in 1912), and a fifth lecture was given by Sabouraud every year until his death in 1938. Three mycologists of the Pasteur Institute, trained as microbiologists – Segretain, Mariat, and Drouhet – but oriented their research work and teaching principally towards medical mycology after 1946. After the death of Magrou in 1951, an annual postgraduate course in medical mycology was set up in 1953. Twenty-four participants – graduates in medicine, veterinary sciences, pharmacy, and science – particularly interested in teaching and research are enrolled annually: two-thirds from France and one-third from other countries, principally Europe, Latin America, and Africa. The course covers all aspects of fungi and actinomycetes that cause diseases in humans and animals and provides extensive practical laboratory work full time. After theoretical and practical examinations, a diploma is awarded by the Institute Pasteur. This course has trained more than 1 000 medical mycologists. There are now more than 15 university centers in the principal cities of France, in which advanced medical mycological teaching is given (Drouhet 1991).

At the Centraalbureau voor Schimmelcultures, Baarn, in the Netherlands, courses on medical and veterinary mycology were organized by de Vries since 1953; now these are organized by de Hoog and provide for an international group of students. Another important course in tropical mycology was given every year at the Institut de Médecine Tropicale Prince Leopold, Antwerp; it was started by Vanbreuseghem.

HISTORICAL EVOLUTION OF THE DIAGNOSTIC MYCOLOGY LABORATORY

The evolution of laboratory diagnoses from the classic conventional methods to the modern, rapid techniques in general followed a similar course to that in microbiology and other new and developing disciplines (immunology, electron microscopy, molecular biology). Their progress contributed, to a great extent, to the development of medical mycology.

The discovery of the microscope (first mentioned by John Faber around 1625) was followed by its application to the study of fungi in nature (Hooke 1665; van Leeuwenhoek 1673; Malpighi 1679; Micheli 1729; Pasteur 1861) and only later, at the turn of the century, to the study of fungi involved in human and animal infections. Phase contrast microscopy, invented by the Dutch physicist F. Zernicke (recipient of a Nobel Prize in 1932), prepared the way for the introduction in the 1950s of transmission electron microscopy (TEM). This was introduced in medical mycology only in the 1960s (Garrisson 1983). It was followed by the apperance of scanning electron microscopy (SEM); both electron microscopic techniques have had a broad application to fungal studies since the 1970s (Cole 1986). Fluorescent microscopy using nonspecific staining procedures (calcofluor white) has been used since the 1980s; specific immunolabeling, which has developed since 1956 as a result of Coon's labeling of protein with fluorescent substances, has become an important tool for the immunological diagnosis of mycoses. Fluorescent microscopy was successfully applied to medical mycology by Kaplan and Kaufman (1961), Drouhet et al. (1972), and others, and was reviewed by Kaufman and Reiss (1986), Longbottom (1986), and Drouhet (1988). Immunoperoxidase (IPO), using an anti-IgG serum label attached to the peroxidase, rather than to fluorescein isothiocyanate, has proved to be as valuable as the immunofluorescent method.

Microscopic detection of fungi in clinical preparations (KOH/NaOH, lactophenol cotton blue, India ink) is made on smears or histological sections stained first with classic stains used in bacteriology and parasitology, such as Gram's stain (1884), May–Grünwald–Giemsa (Wright's) stain, which are based on methylene blue eosinates (1902), hematoxylin–eosin–saffran (HES) (1911) and mucicarmine. Later, two fungus-specific stains superseded all others, namely:

1. the periodic acid–Schiff (PAS) stain based on the same Schiff reagent as that used in Gram's stain, introduced in 1947 by Hotchkiss–MacMannus with Kligman and Mescon's modification (1950), and
2. Gomori's (1946) and Grocott's (1955) silver methenamine stain (GMS).

These two stains that color the cell wall distinctly red (PAS) or black (GMS), are used universally by histopathologists (Baker 1957, 1971; Chandler et al. 1980).

Culture of fungi evolved after the creation of Raulin's first chemically defined liquid medium under standardized conditions, from cultures on shallow porcelain dishes to glass flasks or tubes sealed or plugged with

cotton wool to prevent contamination (Pasteur 1861; Roberts 1874). The use of solid media, such as gelatin, used in 1852 by Vittadini for culture of *Botrytis (Beauveria) bassiana*, was followed by use of agar poured onto glass dishes – a simple technique described by the German bacteriologist Petri (1887), one of Koch's assistants. The agar Petri dish technique, which allowed isolation and identification by morphogenesis, was adapted for bacteriology and mycology. In his early work, Sabouraud (1896, 1910) grew dermatophytes on a variety of solid media and noted that their colony characteristics and microscopic features differed considerably on the various media. Sabouraud's glucose medium became the most widely used in medical mycology, not only for dermatophytes, but also for the isolation and routine subculture of most fungal pathogens (Odds 1991). Later, it was modified by the addition of thermostable antibacterial antibiotics (chloramphenicol, 1947; gentamicin, 1969) and cycloheximide (Acti-Dione) for the selective isolation and identification of pathogenic fungi (Georg et al. 1954). A new culture medium called the dermatophyte test medium (DTM), based on a modification of Sabouraud's medium by the addition of a pH indicator and cycloheximide which inhibits saprophytic mold, led to a simplified and rapid detection of dermatophytes. Many natural media (potato dextrose, potato–carrot–bile, and malt extract agars) or chemically defined media with essential carbon and nitrogen compounds, vitamins or growth factors such as oleic acid for lipophilic yeasts have been described for particular groups or single species of yeasts and molds (Saint-Germain and Summerbell 1996).

Important improvements allowed for the rapid isolation of fungi from blood (lysis–centrifugation system, non-radiometric CO_2 detection, after the 1980s), rapid yeast identification procedures, germ tubes for *Candida albicans*, assimilation tests using C and N compounds (up to 32 carbon sources) by a scaling down of old techniques (described by Beijering in the 1800s, by Wickerham in 1948, and transformed and developed as commercial kits on microplate systems, including rapid enzyme identification, e.g. phenol oxidase developed by Staib 1962, urease, etc.). All these new procedures have been reviewed (Pincus et al. 1988; Roberts et al. 1992; Salkin et al. 1994).

The immunoidentification of fungal pathogens by exoantigens, soluble immunogenic macromolecules produced by fungi, has been intensively developed and standardized by Kaufman and Standard since 1978. The earliest attempt to identify fungi by their soluble antigens was made by Manyck and Sourek in 1966, when they used a single-diffusion tube precipitin test and inoculated cultures of *B. dermatitidis*, *C. immitis*, *H. capsulatum*, and *P. brasiliensis* on the surface of serum agar; their test required up to 21 days to complete, however. Extensive studies carried out since 1983, by Kaufman et al., using standardized rapid procedures with specific reference antigens, allow the identification of most dimorphic fungi, hyaline and pheoid fungi in 2–5 days.

Since 1990, DNA probes have been developed for the rapid identification of those medically important fungi (*H. capsulatum*, *B. dermatitidis*, *C. immitis*), for which conventional techniques are time-consuming. Probe assay results are available within 2 hours compared with the 72 hours for exoantigen tests (Roberts et al. 1992; Mitchell et al. 1994).

IMMUNODIAGNOSIS OF INVASIVE, DEEP MYCOSES

The need for sensitive, rapid, routine, standardized tests for the immunodiagnosis of these mycoses has become increasingly important, and the detection of circulating fungal antigens and serum antibodies has been emphasized in recent reviews (de Repentigny and Reiss 1984; Longbottom and Austwick 1986; Drouhet 1988, 1993b; Buckley et al. 1992; de Repentigny et al. 1994). A new discipline, molecular immunology in medical mycology, was developed (Reiss 1986).

Fungal antibodies

Over the last decades, important progress has been made in the detection of specific serum antibodies as a result of improved antigen preparation and the techniques of immunodiffusion in gels and immunoelectroprecipitation.

These methods were developed at the Pasteur Institute: in 1946, Oudin's gel precipitation method using simple and double diffusion (DD) in tubes, followed in 1948 by Ouchterlony's modification of his practical DD plate technique carried out in Petri dishes. Important improvements were achieved by Grabar and Williams in 1952 with the introduction of immunoelectrophoresis, which combined gel electrophoresis with immunodiffusion. In 1959, Bussard described counter-immunoelectrophoresis (CIE), a highly sensitive and rapid method based on the migration of antigens towards the anode and antibodies towards the cathode in a gel (agarose) at pH 8.2. The two-dimensional immunoelectrophoresis (2DIE) technique was described by Ressler in 1960 and developed by Laurell in 1965 under the name crossed immunoelectrophoresis. In mycology this method made a significant contribution to the identification and characterization of the complex antigens of the fungi and to the antigenic interrelationships of antigenic preparations of species and genera. In 1973, Axelsen first applied 2DIE to the antigenic mosaic of *C. albicans* which is made up of at least 78 antigens, including several major ones. Numerous variants have been reviewed (Axelsen 1973; Longbottom 1986).

Specific enzyme staining techniques applied to immunodiffusion and immunoelectrophoresis of pathogenic fungi started with the work of Uriel in 1963 at the Pasteur Institute. The French school of Biguet showed that the principal precipitating antigen–antibody complexes have enzymatic activities of diagnostic interest, such as the activities of chymotrypsin and catalase for *A. fumigatus,* of chymotrypsin and malic dehydrogenase for *A. flavus*, of malic dehydrogenase activity for *Candida* spp., and of catalase and glucuronidase activities for *H. capsulatum.*

The first enzyme immunoassay (EIA) techniques were described independently by Avrameas and Guilbert in 1971 at the Pasteur Institute and by Engvall and Perlman who gave the name ELISA to enzyme-linked immunosorbent assay. Subsequently, this test was rapidly and extensively applied to the immunology of pathogenic fungi and their respective mycoses. These tests provide an objective end point; they can be automated and are simple to carry out. In addition, they have a sensitivity and specificity comparable to radioimmunoassay (RIA), which is capable of detecting nanogram amounts of antigens and antibodies. Various adaptations of EIA, particularly the enzyme-linked immunoelectrotransfer blot or Western blotting technique developed by Towbin in 1979 and Burnett in 1981, have been reported and compared with other immunological tests (Mackenzie 1983, 1996; de Camargo et al. 1984; de Repentigny and Reiss 1984; Longbottom 1986; Drouhet 1988; Guesdon et al. 1988; de Repentigny et al. 1994).

CIRCULATING FUNGAL ANTIGENS

Research on fungal circulating antigens received considerable attention, principally because of the evolution of systemic opportunistic mycoses in immunocompromised or AIDS patients.

Since the First International Symposium on Fungal Antigens held in 1986 at the Pasteur Institute in Paris, during which many problems in isolation, purification and detection of principal fungal antigens were analysed, new tests for the detection of circulating antigens have been developed for aspergillosis, candidiasis and cryptococcosis; these tests are rapid, routine and commercially available, compared with other reference tests (Drouhet et al. 1988a; Drouhet 1989, 1993b; Buckley et al. 1992; de Repentigny et al. 1994).

Historically, the first circulating antigen was the polysaccharide galactoxylomannan from *C. neoformans*, which was detected by Neil and colleagues in infected animals (Neil and Kapros 1950) and later in humans (Neil et al. 1951). In 1961, Bloomfield et al. developed a simple rapid reactive test for antigen detection in body fluids by latex particle agglutination (LAT), using 0.8 mm particles coated with a polyclonal rabbit anti-*C. neoformans* IgG. This was an extremely sensitive and reliable test when standard conditions were used. The monoclonal antibodies, first reported in 1975 by Kohler and Mildstein, were successfully applied by Dromer et al. (1987) for *C. neoformans* galactoxylomannan antigen detection. Monoclonal antibodies against the mannan of *C. albicans* and galactomannan of *A. fumigatus*, prepared by Stynen (Diagnostics Pasteur 1989), were successfully used in invasive candidiasis (Georges et al. 1991) and aspergillosis (Dupont et al. 1990), respectively; these have high specificity but less sensitivity than the tests for cryptococcosis.

Numerous circulating antigen tests have been performed not only by LAT, but also by EIA and RIA, using monoclonal and polyclonal antisera from cell wall polysaccharides, heat labile glycoproteins (*C. albicans*), cytoplasmic thermostable glycoprotein and 48 kDa protein (*C. albicans*), 18, 32, 92 kDa proteins (*A. fumigatus*) or yeast or spherule forms of dimorphic fungi (*H. capsulatum*, *C. immitis*). Most of these rapid tests are now commercially available (Drouhet 1993b; Dromer 1993).

SENSITIVITY TESTING OF ANTIFUNGAL AGENTS

Although in bacteriology the necessity of laboratory sensitivity followed soon after the discovery of antibiotics, in 1945–50, by disk sensitivity and minimum inhibitory concentration (MIC) testing under standardized conditions (microdilution techniques), in medical mycology the use of in vitro tests and the assay of drugs in body fluids only started in the 1970s with flucytosine (5-FC); this resulted from the emergence of primary or secondary resistant strains and a need to monitor body fluid levels. The tests have also become available for the azoles since the 1980s. Disk as well as diffusion and microplate automated techniques became easier to carry out and were standardized for the in vitro evaluation of antifungal agents against yeasts and sporulating pathogenic fungi (Drouhet et al. 1986), but not for filamentous nonsporulating fungi or dimorphic fungi (Galgiani et al. 1992). Physicochemical methods were used mainly for assays of drugs in body fluids. The methodology, development, and standardization for these tests have been reviewed (Speller 1980; Drouhet and Dupont 1986; Drouhet et al. 1986; Iwata and Vanden Bossche 1986; Galgiani et al. 1992; Van Cutsem et al. 1994; Vanden Bossche et al. 1994).

FINAL CONCLUSIONS

Since the beginnings of the concerted interest in medical mycology which began at the turn of the last century, with the discovery of the principal agents of human and animal mycoses, there has been constant progress in our knowledge of the pathogenic fungi that cause mycotic diseases.

The opportunistic pathogenic fungi and their resultant mycoses, which have emerged in the last few decades under new environmental and host conditions, have reinforced the place of medical mycology as a key component of microbiology. This became possible as a result of the work of the pioneers of medical mycology: enthusiastic medical mycologists, who founded the ISHAM in Paris in 1954, which, with its affiliates, now has more than 1 000 members in medical mycology throughout the world.

The evolution over the last 50 years in the spectrum of fungal infections, their clinical and pathological features, and the ecology and epidemiology of pathogenic and opportunistic fungi has been accompanied by an increased understanding of the fungal cell. Our knowledge of the physiology, biochemistry, immunology, morphogenesis, ultrastructure, sexuality, genetics, and molecular biology of many pathogenic fungi in humans and animals has advanced enormously, but it still needs further intensive investigation.

The need for education and training in medical mycology, as with all closely related basic and applied scientific disciplines, requires further development, with the objective of resolving the burning issues of fungal disease, such as mycoses in high-risk individuals and immunocompromised patients, immunological defence, the cost-effective management of life-threatening mycoses, and the rapid and early detection of infection.

> Taxonomy is often regarded as the dullest of subjects, fit only for mindless ordering and sometimes denigrated within science as mere 'stamp collecting.' If systems of classification were neutral hat racks for hanging the facts of the world, this disdain might be justified. But classifications both reflect and direct our thinking. The way we order represents the ways we think. Historical changes in classification are the fossilized indicators of conceptual revolutions. (Gould 1996)

ORIGIN OF THE FUNGI

The evolutionary origins of biology began with the prokaryotes, the Archaea, and Eubacteria. The Eukaryota, or eukaryotes, are believed to have evolved from prokaryotes about 1.6–2.1 billion years ago with the emergence of protists (Javaux et al. 2001). The protists include protozoa, certain algae, and fungal-like organisms, the Oomycota. Eukaryotic cells are distinguished by a cytoskeleton and intracellular organelles, which are usually enclosed by membranes. The endomembranes of eukaryotic cells include the nuclear membrane, endoplasmic reticulum, Golgi apparatus, peroxisomes, and the plasma membrane. Most of the DNA is organized into chromosomes and contained with the nucleus, but DNA is also found in the mitochondria (in fungi and animals) as well as in extrachromosomal forms. The cytoskeleton includes major proteins that evolved early and have been conserved throughout the evolution of eukaryotes, such as tubulin (which forms microtubules) and actin (microfilaments).

Two major lineages arose early, one led to the algae and terrestrial plants, and the other gave rise to fungi and animals (Figure 1). The common origins of animals and fungi are supported by phylogenetic analyses of the nucleotide sequences of several conserved genes, such as the small subunit (SSU) 18S and large subunit (LSU) 26S of ribosomal DNA (rDNA), elongation factor, tubulin, and actin (Bruns et al. 1991; Baldauf and Palmer 1993; Wainright et al. 1993), although not by sequences of the RNA polymerase II gene (Sidow and Thomas 1994). Based on phylogenetic studies, molecular clock estimations of the rate of mutation, and limited fossil data, the time when animals and fungi diverged has been estimated at approximately 1.5 billion years ago (Heckman et al. 2001; Hedges et al. 2004).

Most fungi grow vegetatively as yeasts or molds, and fungal cells may have more than one nucleus. Similar to other eukaryotes, fungi typically contain mitochondria, a Golgi apparatus, and endoplasmic reticulum. They also contain vacuoles, but lack chloroplasts and pseudopodia. Most have cell walls composed of chitin and β-glucans, as well as other polysaccharides, proteins, and lipids.

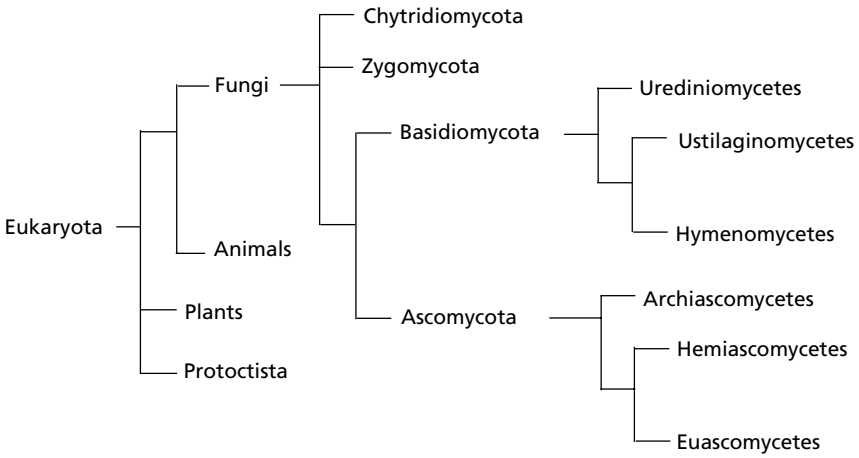

Figure 1 *Major kingdoms of the Eukaryota, the four phyla of the Fungi, and the three classes of the Basidiomycota and the Ascomycota.*

Collectively, fungi exhibit a rich diversity, inhabit every ecological niche on the planet, and manifest a variety of lifestyles. Most fungi are chemotrophic and secrete catabolic enzymes that digest vicinal substrates, which are absorbed, as are minerals, salts, and other small molecules, by passive or active transport mechanisms. Fungi distinctively utilize α-aminoadipic acid in the biosynthesis of lysine. As saprobic fungi proliferate in aquatic and terrestrial locales, they degrade organic substrates for their nutrition, and in the process recycle the organic detritus of plants and animals. Other fungi are exploited by industry for the production of secondary metabolites or pharmacological compounds. Some serve science as model eukaryotes for the study of cellular, molecular, and genetic processes (e.g. *Saccharomyces cerevisiae*, *Neurospora crassa*). Many provide gustatory pleasure, either directly (edible mushrooms, truffles, morels) or indirectly (bread, cheese, alcoholic beverages). Certain groups of fungi are intriguingly specialized, and have the ability to entrap nematodes, form symbiotic relationships (lichens), nourish or protect plants (mycorrhizae and endophytes, respectively), or produce disease in plants or animals. More than 80 000 species of fungi have been described, but the total number of extant fungal species has been estimated to be about 1 500 000 (de Hoog et al. 2000; Kirk et al. 2001). Compared to the enormous kingdom of fungi, the number of infectious, or mycotic, species is minuscule. Nevertheless, the medical fungi exert a profound, global impact on human health. Their numbers continue to increase, but no one knows how many human pathogenic fungi exist. To date, approximately 400 clinically relevant species have been described (de Hoog et al. 2000; Kirk et al. 2001; Howard 2003).

CONCEPTS AND TERMS

Systematics aims to describe and organize biological diversity, usually by determining the phylogenetic relationships among organisms. Systematicists study the relationships of organisms and the processes by which they evolved and are maintained. Classification is the assignment of organisms to defined groups. Systematics entails nomenclature and taxonomy, the science of naming and classifying organisms. Because of their historical association with plants, the fungi are named according to the rules established by the International Code of Botanical Nomenclature. However, reflecting their affinity with animals, the higher fungal groups are called Phyla, not Divisions. Major taxonomic groups of fungi are denoted by the following suffixes: Phylum, -mycota; Subphylum, -mycotina; Class, -mycetes; Subclass, -mycetidae; Order, -ales; Suborder, -ineae; Family, -aceae; and Subfamily, -oideae. The basic taxon is the species. However, the species name is often the antepenultimate rank of classification, just above the variety and individual (Kirk et al. 2001).

Each species is identified by its genus and species name, followed if necessary by a varietal or subspecies designation. A full descriptor of a given species will include the binomial in Italic font followed in non-Italic font by the surname(s) of the author(s) who first described and named the species and the year of its publication, for example, *Cryptococcus neoformans* (Sanfelice) Vuillemin (1901). If a species name is modified, the names of subsequent authors may be added. Whenever possible, the original isolate from which the species was described becomes its permanent reference or the type strain for that species, and it is deposited in an established culture collection (e.g. American Type Culture Collection, Centraalbureau voor Schimmelcultures). If a species is inadvertently described more than once, its name reverts to the original description (with sanctioned exceptions for names with longstanding familiarity).

There are several definitions of a fungal species (Taylor et al. 2000; Burnett 2003). Members of a species are quite similar, if not identical, in their morphology,

mode of reproduction, physiology and temperature range, biochemical structure, ecology, and genomic sequence. Species have been historically demarcated on the basis of morphological and other phenotypic similarities. Biological species are defined by mating compatibility, the abilities to engage in sexual reproduction and successfully interbreed, thus sharing a common gene pool with other members of the species (Burnett 2003). Other criteria have been used to define certain species, including both ecological isolation in nature and the host specificity of pathogenic fungi. Species may also be identified by phylogenetic analyses, using molecular markers as characters to determine evolutionary relationships. Phylogenetic criteria define a species as the smallest recognizable population of individuals or lineage united by shared derived characters (synapomorphy) (Burnett 2003; Vilgalys 2004). Molecular studies have discovered situations where organisms were morphologically indistinguishable, similar in numerous other phenotypes, and occupied the same habitat (sympatric), but they were not members of the same species. One such cryptic species is *Candida dubliniensis*, which was long misidentified as *Candida albicans* (Sullivan and Coleman 1998; Sullivan et al. 2004). Another example is the discovery that the common cause of coccidioidomycosis, *Coccidioides posadasii*, was for decades subsumed by the phenotypically similar species, *Coccidioides immitis* (Fisher et al. 2002).

An important route to speciation occurs when organisms become geographically and reproductively isolated (allopatry). Over time, mutations accrue, selective pressure or genetic drift may impact the organisms, and they become sufficiently divergent that mating with the ancestral population is no longer possible. Advances in fungal genomics are beginning to discover some of the genetic mechanisms that may drive speciation, including mitotic recombination (parasexuality), gene duplications, and chromosomal rearrangements and translocations (Lynch 2002; Wong et al. 2002; Dujon et al. 2004).

The sexually reproductive life cycle of a fungal species is its teleomorph, which indicates that the species has the ability to undergo meiosis and produce meiospores. The anamorph refers to mitotic or asexual reproduction. If a teleomorphic species produces multiple anamorphs, they may be called synanamorphs. Since many fungal species lack a known teleomorph, or were described before their sexual reproductive mode was recognized, their names were based on their anamorphic or asexual reproductive morphology and ontogeny. This method of classification relies on morphology and other phenotypes, and it may or may not reflect evolutionary relationships. Many fungi have both a teleomorphic and one or more anamorphic species names, reflecting their separate description at different times and places. The teleomorph, anamorph, and any synanamorphs of a fungal species comprise its holomorph.

Furthermore, the reproductive structures of many fungal species are indistinguishable. Mating between fungal isolates usually constitutes evidence of species identity. However, isolates with identical anamorphs may not be recognized as different species if they are incapable of sexual reproduction. Consequently, an anamorphic 'species' may represent more than one teleomorphic species, and vice versa. The dermatophytes offer good examples: the geophilic anamorph *Trichophyton terrestre* may represent three different teleomorphs, *Arthroderma quadrifidum*, *Arthroderma insingulare*, or *Arthroderma lenticulare*. Similarly, the teleomorphic species *Arthroderma uncinatum* has two anamorphs, *Trichophyton ajelloi* and *Trichophyton phaseoliforme* (Summerbell and Kane 1997).

The apparent predominance of anamorphy among mycotic fungi may be advantageous for pathogenicity. Asexual fungal species tend to consist of one to several distinct clones or lineages, and sexual reproduction is limited or absent. Evolution occurs by various genomic mechanisms, as noted above, and the gradual accumulation of spontaneous mutations (Taylor et al. 1999b; Taylor et al. 2000; Xu and Mitchell 2002). The environmental growth conditions will subsequently promote the positive selection, survival, and proliferation of clones with favorable mutations. By contrast, sexual reproduction offers the opportunity to more rapidly exchange genetic information. However, in sexually reproducing populations, favorable combinations of mutations that arise in some lineages may be lost through subsequent recombination. Many fungi exhibit a mixture of both clonal reproduction, which can be favored under uniform growth conditions, and sexual recombination, which can be advantageous in changing environments. Perhaps as commensal and pathogenic fungi become more entrenched on the mammalian host, their need for genetic variation is minimized, and anamorphy becomes an important survival mechanism. The dermatophytes exemplify support for this concept. Except for *Trichophyton mentagrophytes* and *Microsporum canis*, the anthropophilic and zoophilic species exist only as anamorphs (e.g. *Trichophyton rubrum*, *Trichophyton tonsurans*, *Trichophyton verrucosum*, *Trichophyton equinum*, *Microsporum ferrugineum*, *Epidermophyton floccosum*), but most of the saprobic, geophilic species have teleomorphic states (e.g. *Microsporum cookei*, *Microsporum gypseum*, *Microsporum persicolor*) (Howard et al. 2003). The evolution to anthropophilism can also be associated with the loss of asexual sporulation. Routine cultures of most geophilic species regularly manifest both macroconidia and microconidia, but many human pathogens tend to produce only, or predominantly, microconidia (*Trichophyton soudanense*, *T. rubrum*, *T. tonsurans*, *Trichophyton yaoundei*), macroconidia (*E. floccosum*), or neither (*Microsporum*

audouinii, *M. ferrugineum*, *Trichophyton concentricum*, *Trichophyton schoenleinii*, *T. verrucosum*, *Trichophyton violaceum*).

Phylogenetics is the taxonomical classification of organisms that reflects their evolutionary relationships. Using molecular or phenotypic characters, a phylogenetic tree depicts the ancestor–descendant relationships among organisms. Morphology – macroscopic, microscopic and ultrastructural – provided the original basis for classifying fungi, as well as other organisms, and proposing phylogenetic relationships. Molecular methods include comparative analyses of the nucleotide sequences of RNA and DNA and the amino acid sequences of proteins (Hillis et al. 1996a). The most comprehensive phylogenies have been constructed from comparisons of the highly conserved nucleotide sequences of ribosomal RNA, especially alignable regions of the small (18S) and large (26S) subunits (SSU and LSU) of rDNA.

A cluster of taxa on a branch of a phylogenetic tree or clade is monophyletic if all organisms in that group are known to have developed from a common ancestor, and all descendants of that ancestor are included in the group. A group is paraphyletic if all the members have a common ancestor but the group does not include all the descendants of the common ancestor. Taxonomic groups that contain organisms but not their common ancestor are called polyphyletic. Phylogenetic classifications aim to group species such that every group is descended from a single common ancestor, and the elimination of groups that are found to be polyphyletic often stimulates major revisions of the classification.

PHENOTYPES AND MOLECULAR MARKERS TO IDENTIFY FUNGI

As summarized in Table 1, traditional methods of classifying fungi utilize phenotypic differences in vegetative and reproductive morphology (e.g. colonial and micromorphology), physiology (e.g. patterns of assimilation and fermentation, temperature, and pH range of growth), the presence of structural macromolecules (e.g. cell wall polysaccharides, isoprene units of coenzyme Q), and sexual mating. Since most medical fungi do not evince a teleomorph, their identification and classification have rested on phenotypic characteristics. Definitive phenotypic features are often difficult to discern or highly variable. Thus, for many pathogens, the species boundaries are loosely defined. For example, any elliptical, fermentative, nonpigmented, asexual yeast producing multilateral buds and pseudohyphae is likely to be placed in the genus *Candida*, which is large, multifarious, and polyphyletic (Meyer et al. 1998; Diezmann et al. 2004).

Molecular markers are definitive and more stable than most phenotypic attributes, and they are helping to resolve these issues. There is continuing progress in the biotechnology of rapid, high-throughput methods to genotype strains and the development of innovative statistical approaches and software to analyze the data. Some of the more common DNA-based methods are listed in Table 2, discussed in Laboratory diagnosis, and detailed in recent reviews (Bruns et al. 1991; Taylor et al. 1999a; Mitchell and Xu 2003; Taylor and Fisher 2003).

Table 1 *General phenotypic approaches to identify and characterize fungi*

Phenotype category	Observations (examples)
Morphology	Teleomorph: Sexual reproduction (zygospore, ascocarp, basidiocarp) Anamorph: Mitospore ontogeny and morphology (sporangia, conidiogenesis) Vegetative yeast or hyphal morphology (septate, dematiaceous, Diazonium Blue B) Colony texture, pigment, size Septal pore type Dimorphism
Structural macromolecules	Cell wall polysaccharides (chitin, glucans, mannans) Coenzyme Q isoprene units Isozymes Antigens
Metabolism	Assimilation of particular compounds as sole nitrogen or carbon sources Fermentation of various carbon compounds Metabolic pathways Vitamin requirements (biotin, thiamin) Production of enzymes (proteases, phospholipases, urease, catalase, etc.) Secondary metabolites (mycotoxins)
Growth parameters	Optimum and tolerable range of temperature, pH, concentration of salts, oxygen requirements, etc.
Susceptibility to inhibitors	Inorganic compounds (chlorine salts) Fungicides, detergents, organic compounds (canavanine, benomyl, etc.) Drugs (antifungal antibiotics, cycloheximide) Killer yeasts
Pathogenicity	Host range Virulence factors (adhesins, secretory enzymes, etc.)

Table 2 *General DNA-based methods in medical mycology*

Method	Application		
	Strain identification, molecular epidemiology, population genetics	Species identification	Phylogenetics and systematics
Electrophoretic karyotype	✓		
RFLP	✓	✓	
Southern hybridization	✓	✓	
RAPD, PCR fingerprint, AFLP	✓	✓	
Microsatellites	✓	✓	
Microarrays	✓	✓	
SNP, MLST, DNA sequencing	✓	✓	✓

Abbreviations: AFLP, amplified fragment length polymorphism; MLST, multilocus sequence typing; RAPD, random amplified polymorphic DNA; RFLP, restriction fragment length polymorphism; SNP, single nucleotide polymorphism, detected by high-throughput, automated system. Microarray technology is currently only theoretical.
Other methods: mol% G+C; DNA–DNA hybridization.
References: Bruns et al. 1991; Mitchell and Xu 2003; Taylor and Fisher 2003.

A molecular marker is defined as any identifiable region of the genome. Some markers are better at discriminating individual strains, discrete species or higher taxonomic groups. For certain studies, it is desirable to use markers in specific genes, and for others, markers in noncoding, usually anonymous portions of the genome are preferable because they are assumed to be neutral or unaffected by selective pressure. Molecular markers for fingerprinting medical fungi include allozymes, electrophoretic karyotypes, DNA hybridization probes, PCR-based genotypes, endonuclease restriction fragment length polymorphisms (RFLP), and DNA sequencing (Table 2).

The comparison of nucleotide sequences among species has revolutionized phylogenetic studies. The most reliable DNA markers identify nucleotide sequence polymorphisms, such as single nucleotide polymorphisms (SNP), insertions or deletions (indels), and length variations in tandem oligonucleotide repeats (microsatellites). Such markers can be detected by an array of molecular techniques, such as PCR amplicon length polymorphisms, differences in the lengths of RFLP, single-strand conformational polymorphisms (SSCP), or direct DNA sequencing of homologous genomic regions of the strains or species under comparison [multilocus sequence typing (MLST)]. These methods and their applications to fungal phylogenetics have been described in several reviews (Berbee and Taylor 1999; Taylor et al. 2000; Mitchell and Xu 2003; Taylor and Fisher 2003). Some methods are more suitable for population and phylogenetic studies of closely related taxa and strains of a species, such as isozymes (see below), amplified fragment length polymorphisms (AFLP), randomly amplified polymorphism DNA (RAPD), and hybridization of nucleotide probes to electrophoretic blots of digested genomic DNA (Bakkeren et al. 2000; Soll 2000; Mitchell and Xu 2003).

Protein polymorphisms, such as isozymes, provide excellent markers for population genetics, but they are not widely applicable for large phylogenetic investigations. They usually reflect nucleotide sequence differences resulting in the substitution of one or more amino acids, which alter the chromatographic mobility of the protein to enable detection (Brandt et al. 1993; Murphy et al. 1996; Mitchell and Xu 2003).

In summary, these markers and the attendant analytical software have greatly innovated the methods to:

- resolve taxonomic uncertainties
- investigate the transmission of strains in local outbreaks
- accurately identify fungi in clinical specimens
- recognize strains with clinically important phenotypes (e.g. virulence factors, resistance to antifungal drugs)
- analyze the genetic structure of populations of a pathogen
- trace the evolution of mycotic species
- validate the medical relevance of strains used in basic research, comparative genomics, and the development of new antifungal antibiotics and diagnostic tests.

PHYLOGENETIC METHODS

The sequences of any two or more related taxa can be compared to detect phylogenetic relationships. The underlying assumptions are that with the passage of time, there is an increase in the number of mutations, divergence, and phylogenetic distance between organisms and their genomic sequences. The ‘molecular clock’ hypothesis assumes that molecules evolve in direct proportion to time; consequently, the differences between homologous DNA sequences (or proteins) can be used to estimate the elapsed time since the two DNA sequences (or their taxa) last shared a common ancestor (Hillis et al. 1996b; Hedges and Kumar 2004). However, the observed rate at which nucleotides change is not constant. Some sequences exhibit less variation over

time than expected because their functionality is essential and lethal mutations are lost. This problem is usually obviated by analyzing sequences of noncoding DNA. However, after sufficient time, some nucleotides may undergo further mutation(s) and revert to the ancestral sequence. Most algorithms to construct phylogenetic trees consider such variables and produce a consensus or single 'best' tree with branches of optimal length and likelihood. The common approaches of phylogenetic analysis include Neighbor-Joining (NJ), parsimony, Maximum Likelihood (ML), and Bayesian methods (Xu and Mitchell 2002; Baldauf 2003b; Felsenstein 2003; Holder and Lewis 2003).

The usual phylogenetic methods use algorithms that are based on genetic distances, optimality criteria, such as parsimony or ML, or Bayesian probabilities (Swofford et al. 1996). The first step involves the alignment of nucleotide (or protein) sequences of the taxa being compared. The most popular distance methods are NJ and Unweighted Pair-Group Method with Arithmetic Mean (UPGMA), which estimate phylogenies based on the nucleotide differences among the taxa. Maximum Parsimony (MP) or ML apply optimality criteria to infer phylogenies that minimize the number of evolutionary steps required to explain the data. The selection of one or more methods is governed by the number and diversity of the taxa, as well as the sequences that are compared. Other considerations are the types of assumptions associated with a particular data set (e.g. constant or varying rate) and the required computational power, as algorithms such as ML are more demanding than others.

The products of these methods are phylogenetic trees, which estimate the evolutionary history of a group of sequences. A phylogenetic tree is often rooted with an outgroup of some evolutionary distance from the taxa being analyzed, which anchors the study taxa and provides structure for the tree. Two kinds of diagrams are commonly generated with rooted trees – cladograms and phylograms. A cladogram presents only the nodes and branches. In a phylogram, branch length is proportional to the evolutionary distance, providing a schematic depiction of the number of character state differences (e.g. nucleotide substitutions) between the taxa on that branch. There are several excellent reviews of phylogenetic methods and theory (Hillis et al. 1996a; Swofford et al. 1996; Felsenstein 2003; Holder and Lewis 2003; Hall 2004).

Distance methods approximate a phylogenetic tree by estimating the relative number of nucleotide differences between each pair of taxa in a multiple alignment. This method usually assumes that the rate of mutation for the aligned sequences is neutral, independent, and constant, and that the occurrence of multiple changes of the same nucleotide(s) can be estimated. However, corrections for unequal substitution rates and other variables are commonly introduced. UPGMA is the simplest clustering algorithm, which starts with the two most similar sequences, and then sequentially adds taxa of increasing genetic distance. UPGMA also assumes that all taxa are equally distant from the root (i.e. assumes a molecular clock) and thus yields symmetrical trees. NJ is a similar distance method but does not assume a molecular clock. NJ initially calculates the net divergence of each taxon from all the others, which is the sum of the individual differences from the taxon. Next, the program selects the pair of taxa that are least diverged and calculates their distances from the node that connects them. This node is substituted for the pair, and the process continues, reducing the matrix with each step. One of the accessible programs for constructing phylogenies is PAUP* (Swofford 2002; Hall 2004). UPGMA and NJ programs are the least computationally demanding of the common methods and run very quickly on most computers. However, their speed sacrifices accuracy, as neither method attempts to optimize a tree to determine the best estimate. By contrast, MP, ML, and Bayesian inferences perform iterative rounds of optimization to find the best tree.

An excellent test of the statistical support for each branch of the tree is bootstrapping, which can be appliedto all methods (Felsenstein 1985). There is some debate about the interpretation of bootstrap values in phylogenetic analyses. For parsimony analysis, bootstrap values >70 percent are usually considered acceptable, but for the other methods, values >90 percent are considered significant support for a clade. Bayesian probabilities often achieve >95 percent support for branches.

Unlike distance methods, MP seeks a tree(s) that requires the minimum number of nucleotide (or other characters) changes. Therefore, MP only needs to analyze informative sites, namely, nucleotide changes that occur in two or more sequences. The algorithm then determines which one or more of the possible tree(s) requires the fewest number of changes.

The ML approach is usually applied to a particular tree or evolutionary model and computes the probability of generating that tree from the dataset. ML seeks to infer the tree with highest probability from the observed sequence alignment.

A Bayesian analysis (BA) undertakes a succession of iterative phylogenetic analyses, each of which employs the optimized parameters of the previous analysis, until a best tree or set of trees is obtained. BA resembles ML, but ML searches for the best tree that maximizes the probability of observing the data for that tree, and BA seeks the tree(s) that maximizes the posterior probability of the tree for that data. BA, which is commonly employed with the MrBayes program, using the Metropolis-coupled Markov Chain Monte Carlo sampling method, is more robust and exhaustive and will determine the best set of trees (Huelsenbeck and Ronquist 2001). These programs do their work by analyzing the alignments, sequentially and repetitively comparing tree configurations to identify the tree or trees with the

highest probability (Huelsenbeck et al. 2001; Holder and Lewis 2003; Hall 2004).

In addition to genomic sequences, other molecular characters and phenotypes are helpful in analyzing phylogenies. Certain cell wall polysaccharides are associated with specific fungi, and the chemical or immunological detection of signature motifs can be used to identify fungi within those groups. Similarly, the capacity to produce secondary metabolites and metabolic byproducts (e.g. arabinitol) under the appropriate conditions have sufficient specificity in clinical settings to be useful in diagnostic and prognostic tests, and these properties may be significantly correlated with certain taxonomic lineages. These structural and metabolic compounds include coenzyme Q, which is a mitochondrial electron carrier with a varying number of isoprene units. The length of the isoprene chain is often the same within a monophyletic group (Yamada et al. 1977). As noted below, pathogenicity is a polyphyletic trait, as it evolved, and was lost, multiple times throughout the history of fungi. Many of the attributes required for virulence by certain fungal species are absent in other pathogens, as well as present in nonpathogens. There are many examples of such properties, including dimorphism, secretory enzymes that catabolize host substrates, and cell wall ligands that promote adhesion to host cell receptors. At least one phenotype seems to be universally required if not necessarily sufficient for systemic fungal infection, growth at 37°C.

GENOMICS

The new disciplines of genomics and bioinformatics offer panoptic approaches to integrate molecular and phenotypic data to elucidate fungal classification and evolution. The number of complete genome sequences of mycotic, phytopathogenic, and model fungi is increasing (www.genome.gov/11008243). These databases permit the comparison of not only genes but entire genomes, and there are multiple ways to exploit these resources. Following completion of the genome sequence of *S. cerevisiae*, sequences of 13 related hemiascomycetous yeasts were compared to evaluate the conservation of chromosome maps and the similarity and synteny among genes (Gaillardin et al. 2000; Malpertuy et al. 2000; Souciet et al. 2000). Data from this ongoing multilaboratory project are regularly updated at the Génolevures ('yeast gene') web site: cbi.labri.fr/Genolevures/. A subsequent comparison of the genomic sequences of *Candida glabrata*, *Debaryomyces hansenii*, *Kluyveromyces lactis*, *S. cerevisiae*, and *Yarrowia lipolytica*, which manifest different reproductive modes, led to the discovery of many new genes and gene families and specific mechanisms whereby these yeast lineages have evolved (Dujon et al. 2004). Comparative genomics approaches are being used to identify phyla and other taxon- or pathogen-specific genes, as well as test the validity of phylogenetic methods (Hardison 2003).

CLASSIFICATION

It has been difficult to resolve the ancestry of fungi and other eukaryotes, and analyses of various taxa and genes have generated inconsistent phylogenies. Several issues contribute to the problem of parsing these ancient lineages:

- there is a dearth of fossil data
- extant ancestral species have saturated their available mutable nucleotides, even back-mutating to their original sequences
- the results vary depending upon the selected taxa, genes, methods, and outgroups (Baldauf 2003a).

Eventually these problems will be surmounted by increasing the number of taxa, using multigene datasets, and refining the phylogenetic methods.

Lacking a consensus about the classification of the deep branches of the eukaryotic domain, a neutral approach has been to place the diverse ancestral phyla within the Kingdom Protoctista, which contains early eukaryotes that do not qualify as plants, animals, or fungi (Figure 1). Some of the 18–20 protoctistan phyla were previously thought to be fungi, such as the Acrasiomycota (cellular slime molds), Myxomycota (plasmodial slime molds), and Oomycota (water molds). The Protoctista also includes the protozoa and algae. Table 3 lists the higher taxa containing pathogenic fungi, including for comparison a few prominent taxa that do not contain mammalian pathogens. At least two human pathogens are included among these 'pseudofungi,' *Rhinosporidium seeberi* in the Mesomycetozoa (Herr et al. 1999; Mendoza et al. 2002) and *Pythium insidiosum* in the Oomycota (Cooke et al. 2000; Tyler 2001).

The true fungi are contained within the Kingdom Eumycota, which is comprised of four phyla, the Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota (Figure 1). Multiple phylogenetic analyses of molecular, morphological and other phenotypic data support the view that the Kingdom Fungi is monophyletic and originated with the Chytridiomycota (Sugiyama 1998). Fungi were classically defined by the limits of mating, and three phyla – Zygomycota, Ascomycota, and Basidiomycota – are named according to the product of sexual reproduction. For asexual fungi, the morphology and ontogeny of their mitosporic reproductive structures became the basis for the artificial form-taxa within the Class Deuteromycetes or Fungi Imperfecti. This alternative approach groups anamorphs according to their morphology, such as yeasts (blastomycetes) and molds (hyphomycetes). However, these morphology-based schemata do not represent phylogenetic relationships and thus do not reflect reliable biological or evolutionary information. Using available SSU rDNA sequences, the phylogram in Figure 2

Table 3 *Higher taxa of mycotic fungi and selected pseudofungi*

illustrates the relationships among many of the medical fungi.

As noted above, traditional classifications of the fungi relied on morphological characters and sexual reproduction (Guarro et al. 1999; de Hoog et al. 2000). These approaches continue to serve well, especially for the identification of taxa. Of course, clinical mycology has more pragmatic goals: to obtain a rapid and accurate identification of a fungal isolate from a clinical specimen. Most human pathogenic fungi are anamorphic, and with rare exceptions (the homothallic ascomycete, *Piedraia hortai*), they are asexual when causing an infection. Therefore, traditional and commercial methods have combined morphological and physiological phenotypic characters to develop keys for the timely identification of fungal isolates from clinical specimens. Expedient shortcuts utilizing physiological tests are especially useful for the rapid identification of yeasts (Freydiere et al. 2001).

Beyond the bedside, clinical mycology benefits from an authentic phylogeny of pathogenic fungi. Knowledge of the lineages and nearest relatives of the mycotic fungi is useful because closely related species share similar genes, macromolecules, and biochemical processes. This information is invaluable in selecting comparative taxa to investigate the specificity of new diagnostic tests and antifungal antibiotics, as well as directing rational studies of pathogenesis, virulence factors, and mechanisms of drug resistance.

Modern systematics uses molecular data to assign asexual species to their likely positions within the taxonomic framework based on their most closely related taxa, as determined by molecular and phenotypic similarities. The ultimate goal – to create a unified taxonomy that reflects the phylogenetic evolution of the fungi – has been facilitated by advances in biotechnology, sequencing, and computer programs to analyze the data. As molecular evolution is the foundation of biology, the aim is to assign asexual species to their proper phylogenetic place in the classification, and it is feasible with sufficient molecular data and analyses. However, molecular data are lacking for many pathogenic anamorphic fungi (and countless saprobic anamorphs). Such species are usually classified with phenotypically similar fungi (Seifert and Gams 2001).

The classification of fungi will continue to be a work in progress for many years. New species are constantly being discovered. The phenotypic and genotypic characterization of each new species allows it to be placed on the mycological tree, which will often lead to refinement and adjustment of various branches of the phylogeny. This ongoing process will further elucidate the relationships among fungi and their evolution. Species, families, and orders will continue to be created, conflated, and reorganized. Thus revision is constant and inexorable, understandably but unfortunately causing some confusion, as familiar fungal names and taxonomic associations are periodically supplanted. This perpetual change is often accompanied by controversy and reasoned disagreement based on conflicting data or differing interpretations of the data.

The protocols for naming new species and higher taxa are well established, and mycologists follow the rules of Botanical Nomenclature. However, there is not a recognized mycological governing body to arbitrate controversies and decide controversial issues. Lacking an official consensus, the classification presented here is an amalgam of several respected sources, including recent publications (de Hoog et al. 2000; Kirk et al. 2001; Howard 2003) and useful web sites, such as Myconet (www.umu.se/myconet/Myconet.html), the Fungal Tree of Life (ocid.nacse.org/research/aftol/), the Index Fungorum (www.indexfungorum.org/Names/Names.asp), Deep Hypha (ocid.nacse.org/research/deephyphae/index.php?id=projects), and the Tree of Life Web Project (tolweb.org/tree?group=Fungi&contgroup=Eukaryotes).

PHYLUM CHYTRIDIOMYCOTA

Members of this phylum are organized into a single class with five orders. The Chytridiomycetes are characterized by motile asexual zoospores, and more than 900 species have been described (de Hoog et al. 2000; Kirk et al. 2001). The Orders Neocallimasticales and Blastocladiales

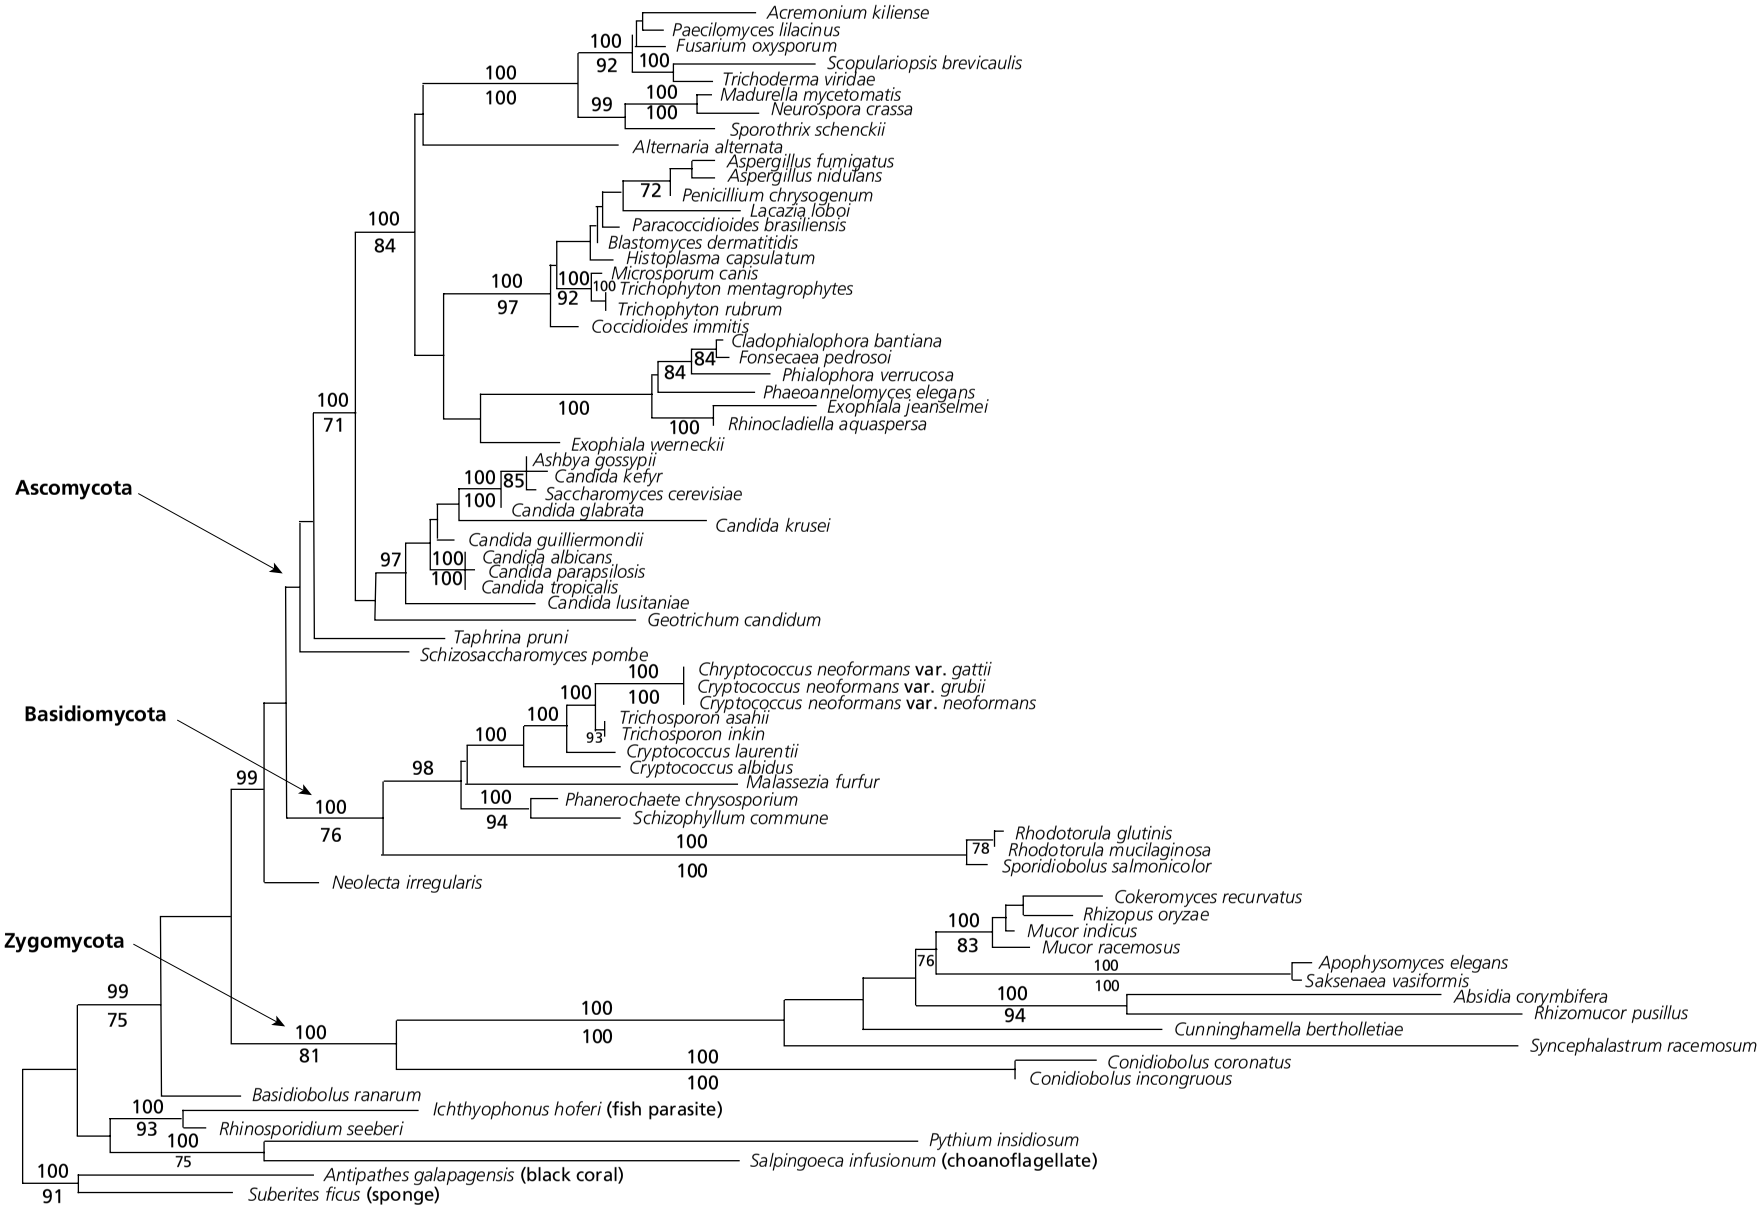

Figure 2 *Phylogram of representative mycotic fungi. Single most likely tree based on a ML analysis of the nuclear SSU rDNA sequences. Nodes with statistically significant support by bootstrap (⩾70 percent) or Bayesian (⩾95 percent) analysis are indicated by the values below or above the nodes, respectively.*

contain intestinal anaerobes and invertebrate pathogens, respectively. The Order Chytridiales has pathogens of nematodes, rotifers, and amphibians. Phylogenetic evidence suggests that both the Chytridiomycota and the Zygomycota are polyphyletic (Sugiyama 1998).

Basidiobolus ranarum may be the sole human pathogen among the chytridiomycetes (Table 3). *B. ranarum* is now recognized as the only pathogenic species of *Basidiobolus*, as previously described mycotic species (viz. *Basidiobolus haptosporus* and *Basidiobolus meristosporus*) are considered synonymous (Ribes et al. 2000). Based on several SSU rDNA phylogenies, *B. ranarum* has been relocated from the Zygomycota to the Chytridiomycota (Nagahama et al. 1995; Jensen et al. 1998; James et al. 2000). As James et al. observed, *Basidiobolus* spp. are the only known nonzoosporic fungi that possess a nucleus-associated organelle (NAO) containing microtubules, although the number and arrangement of the microtubules differ from those of the centriolar microtubules of the chytrids (McKerracher and Heath 1985; James et al. 2000). However, phylogenetic analyses of the α-tubulin and β-tubulin genes provided strong support for classifying *B. ranarum* within the Zygomycetes (Keeling 2003). These discrepant results may be explained by the apparently faster rate of evolution of the SSU rDNA of the chytrids and zygomycetes compared with the tubulin genes (James et al. 2000; Keeling 2003). Another phylogeny of these basal fungi analyzed sequences of the largest subunit of the gene encoding the DNA-dependent RNA polymerase II (*RPB1*), and these results indicated that *B. ranarum* is distantly related to the zygomycetes (Tanabe et al. 2004).

PHYLUM ZYGOMYCOTA

The Phylum Zygomycota has two classes, the Zygomycetes and the Trichomycetes, and together they contain about 1 100 described species (de Hoog et al. 2000; Kirket al. 2001). The Trichomycetes are obligate parasites of arthropods, but two orders of the Class Zygomycetes, Entomophthorales and Mucorales, have important mammalian pathogens. The vegetative hyphae of zygomycetous molds are coenocytic or sparsely septated. The zygomycetes are defined by the mode of sexual reproduction, which is initiated by hyphal anastomosis between compatible mating types of the same species. Mating compatibility is determined by opposite alleles at the mating type locus. Following fusion of the haploid nuclei, meiosis, and one mitotic division, one haploid nucleus usually survives to develop into a zygospore. When exposed to the appropriate growth conditions, the zygospore of Mucorales species will produce a sporangiophore and a sporangium, yielding asexual sporangiospores that germinate to form vegetative haploid hyphae. Most members of the Order Entomophthorales reproduce asexually with forcibly discharged conidia.

The zygomycetous pathogens are listed in Table 4. Within the Entomophthorales, the two classically recognized pathogenic genera, *Basidiobolus* and *Conidiobolus*, cause primary subcutaneous infections and are responsible for subcutaneous phycomycosis and rhinoentomophthoromycosis, respectively (see Subcutaneous zygomycoses). However, as noted above, molecular phylogenies have indicated that *B. ranarum* may be more closely related to nonflagellate chytridiomycetes (Nagahama et al. 1995; Jensen et al. 1998; James et al. 2000).

Most of the pathogens in this phylum are members of the Order Mucorales and agents of the more invasive infection, mucormycosis, whose name refers to the order and not the genus, *Mucor*, which is a rare cause of disease. However, as elaborated in Systemic zygomycosis, most clinical mycologists favor the term 'zygomycosis,' referring to an infection caused by any member of the Class Zygomycetes. The most common agent of invasive zygomycosis in humans is *Rhizopus arrhizus* (*Rhizopus oryzae*) (Ribes et al. 2000).

PHYLUM ASCOMYCOTA

The Ascomycota is the largest fungal phylum, and it embraces 90 percent of the nearly 400 pathogenic fungi (Table 5). Their evolution has been estimated to date from 900 to 500 million years ago (Berbee and Taylor 1993; Taylor et al. 1999; Hedges et al. 2004). Approximately 33 000 ascomycetous species have been described, and they are unified by sexual reproduction that culminates in the production of asci and ascospores (de Hoog et al. 2000; Kirk et al. 2001). In addition, most of the ≈16 000 anamorphic species of fungi, which were first identified according to their conidial mitospores, have been placed within the existing ascomycetous classification based on their molecular and phenotypic affinities. The availability of nucleotide sequences has enabled asexual fungi to be placed with confidence among their closest relatives. The Ascomycota is also home to most of the lichenized fungi.

During vegetative growth, ascomycetous fungi produce either budding or fission yeast cells or branching substrate (vegetative) and aerial (asexually reproductive) hyphae. Hyphal septa possess simple pores that permit cytoplasmic continuity between cells. Some species, including many important human pathogens, are dimorphic, and the morphogenetic conversion to hyphae or yeasts (or spherules) is triggered by environmental signals such as temperature, available nutrients, or carbon dioxide concentration. The Phylum Ascomycota has three classes, the Archiascomycetes, the Hemiascomycetes (yeasts), and the large Euascomycetes (molds). According to SSU rDNA sequence analyses, the Archiascomycetes contains taxa that arose before the latter two classes, which are monophyletic lineages (Bruns et al. 1992; Berbee and Taylor 1993; Nishida and

Sugiyama 1994). Members of the Archiascomycetes are highly diverse, encompassing mycelial species, fission yeasts, and unicellular forms. The genera include many nonpathogens, such as *Protomyces* and *Saitoella*, as well as *Taphrina*, *Schizosaccharomyces*, and *Pneumocystis* (Table 5). Evidence from molecular and biochemical studies indicates that some of these taxa are monophyletic, but the status of others is questionable (Sjamsuridzal et al. 1997). Figure 3 depicts an rDNA phylogeny of representative ascomycetes.

Class Hemiascomycetes

The Hemiascomycetes (yeasts) comprise one large order, the Saccharomycetales, which was established in 1960 by V.I. Kudrjavzev (Kurtzman and Fell 1998; Kirk et al. 2001). The monumental compendium of yeasts, edited by Kurtzman and Fell, lists 42 teleomorphic and 15 anamorphic genera of ascomycetous yeasts (including several genera of Archiascomycetes). The other indispensable resource, written by Barnett et al. (2000), describes 678 species of ascomycetous and basidiomycetous yeasts. Members of the Saccharomycetes are characterized by:

- absent or only rudimentary hyphae
- vegetative cells that reproduce by budding or fission
- cell walls that lack chitin
- asci that are formed singly or in chains (Kurtzman and Fell 1998).

Phylogenetic analyses of SSU rDNA and RNA polymerase II (*RPB2)* gene sequences support a single evolutionary origin of the Saccharomycetales (Berbee and Taylor 1992; Liu et al. 1999). Perhaps the largest phylogenetic analysis of the Saccharomycetes entailed more than 500 species and a comparison of LSU rDNA sequences (Kurtzman and Robnett 1998).

The Saccharomycetales contains many yeasts of medical importance, such as species of *Candida*, which are the most prevalent pathogenic fungi (Table 5; Management of superficial infections; 15, Superficial candidiasis; and 30, Candidiasis) (Calderone 2002). As mentioned earlier, *Candida* is a large and broadly defined anamorphic genus with 163 species (Meyer et al. 1998). They include *C. albicans*, *C. glabrata*, *Candida parapsilosis*, and *Candida tropicalis*. In a recent analysis of the medical yeasts and related hemiascomycetes, DNA sequences of six nuclear genes were analyzed using ML and Bayesian phylogenetic methods to produce the phylogram in Figure 4, which depicts the relationships of the most common mycotic yeasts with rare opportunists and strict saprobes (Diezmann et al. 2004). During the translation of mRNA to polypeptides, several species of *Candida* exhibit alternative codon usage; the codon CUG is translated as serine instead of leucine, as in most other

a) Questionable human pathogen.

eukaryotes (Massey et al. 2003). However, *Candida* is not a monophyletic genus, and species vary in codon usage as well as the number of isoprene units in coenzyme Q and other characters (Diezmann et al. 2004).

Unlike molds, which are identified primarily by observing their colonial and microscopic morphology, yeasts vary little in morphology and are routinely speciated according to a battery of physiological criteria (Freydiere et al. 2001; Hazen and Howell 2003). However, a commercial method has been recently developed for the automated sequencing of the D2 region of LSU rDNA to identify both yeast and mold cultures within 24 hours (Hall et al. 2003, 2004).

Class Euascomycetes

This large class of molds holds most of the Ascomycota, including most of the anamorphic taxa (see Table 5). The phylogenies of numerous groups of Euascomycetes have been analyzed using a number of gene sequences (e.g. SSU and LSU rDNA, *RPB1*, *EF2*) and phylogenetic approaches (e.g. MP, NJ, Bayesian) (Prillinger et al. 2002; Reeb et al. 2004). The number of orders and families remains in flux, and the classification of the Euascomycetes will likely be mutable for many years as there is a steady and natural accrual of new information (Kirk et al. 2001; Prillinger et al. 2002; Eriksson et al. 2004). Some of the more medically relevant groups are described below.

ORDER ONYGENALES

Many notable pathogens are members of the Order Onygenales, which was originally defined using detailed morphological observations and other phenotypic data (Currah 1985). This order is noted for the production of enclosed ascomata, either cleistothecia or gymnothecia. The anamorphs produce distinctive thallic conidia, such as macroconidia, microconidia, chlamydospores, and arthroconidia. Two medically prominent families are the *Arthrodermataceae*, which contains the dermatophytes and related keratinophilic saprobes, and the *Onygenaceae*, which includes the endemic, dimorphic pathogens (Table 5). The more famous onygenalean genera are *Blastomyces*, *Coccidioides*, *Epidermophyton*, *Histoplasma*, *Microsporum*, *Paracoccidioides*, and *Trichophyton*. The *Arthrodermataceae*, *Onygenaceae*, and *Gymnoascaceae* were subjected to a masterful phylogenetic investigation that involved a comparison of sequences of both the SSU and LSU rDNA using NJ and ML methods (Sugiyama et al. 2002). From this analysis of 80 taxa, four major clades emerged. One clade included saprobes and systemic pathogens, while the *Arthrodermataceae* were ensconced in a different clade. Two pathobiological phenotypes, keratinolysis and dimorphism, are likely apomorphic, deriving independently by convergent evolution, as they occurred in taxa in different clades. For example, since *C. immitis* was in a different clade from the *Ajellomyces* spp., pathogenicity and dimorphism are apparently apomorphic (Sugiyama et al. 2002).

Initially described in the 1840s, the dermatophytes are among the earliest documented human pathogens (Howard et al. 2003). The many species of *Microsporum* and *Trichophyton* are closely related and similar in their morphology, physiology, degradative enzymes (e.g. keratinases, elastases), and antigens (Kane et al. 1997). However, some species exhibit marked differences in ecology and host range. As mentioned above, the evolution of dermatophytes toward zoophilism and anthropophilism correlates with the loss of both sexual and asexual sporulation. Most of the clinical species are resolutely anamorphic and defined by subtle phenotypic features. After decades of taxonomic revisions, several molecular phylogenies are finally resolving the phylogeny of the dermatophytes, but classifying dermatophytes remains a dynamic enterprise (Gräser et al. 1999; Makimura et al. 1999).

ORDER EUROTIALES

In the Order Eurotiales, sexual reproduction results in perithecia or cleistothecia, and the anamorphs produce a variety of morphologically distinct conidiophores and phialoconidia. As indicated in Table 5, the family *Trichocomaceae* includes *Penicillium* and *Aspergillus* (Berbee et al. 1995; LoBuglio and Taylor 1995; Summerbell 2003). The Order Ophiostomatales contains the dimorphic *Sporothrix schenckii* and a number of closely related phytopathogens (de Beer et al. 2003). Numerous dematiaceous pathogens are

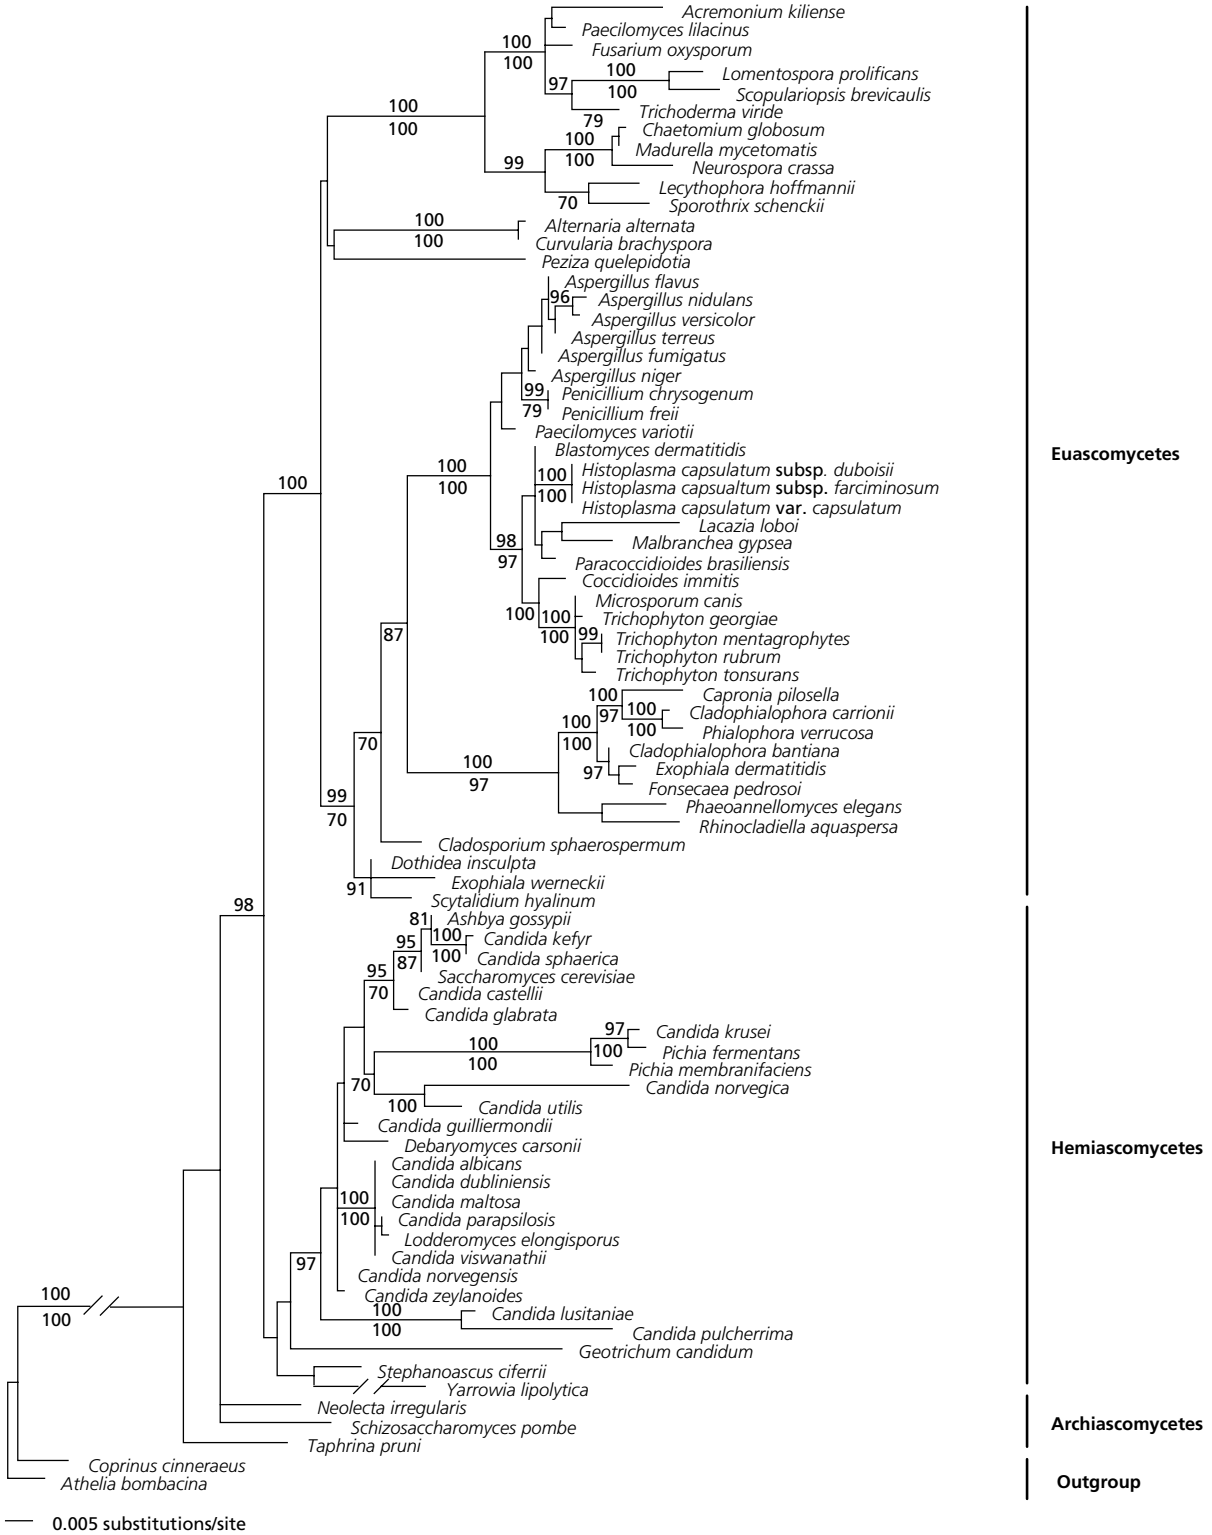

Figure 3 *Phylogram of representative and related mycotic ascomycetes. Single most likely tree based on a ML analysis of the nuclear SSU rDNA sequences. Nodes with statistically significant support by bootstrap (⩾70 percent) or Bayesian (⩾95 percent) analysis are indicated by the values below or above the nodes, respectively. Vertical lines on the right denote the three classes of the Ascomycota.*

classified in the Order Dothideales (Spatafora et al. 1995; de Hoog et al. 1999; Sterflinger et al. 1999). Although the exact phylogenetic placement of these taxa is the subject of ongoing investigations, many familial relationships have been resolved; for example, the family *Herpotrichiellaceae* contains species of

Cladophialophora, *Exophila*, *Fonsecaea*, and *Phialophora* (Haase et al. 1999).

In a superb review of the Eurotiales, which was published in 2003 but apparently written in 2000, Richard Summerbell questioned the validity of many case reports attributable to species of *Aspergillus* (Summerbell 2003). The following species are listed as pathogens in Table 5, but their status as agents of aspergillosis is questionable because of the lack of definitive documentation: *Aspergillus glaucus* group, *Aspergillus reptans*, *Aspergillus restrictus*, *Aspergillus unguis*, *Aspergillus janus*. Of course, many other species of *Aspergillus* have been recovered from patients but are not listed because they were isolated only as contaminants from nonsterile clinical specimens (e.g. skin, sputa, sinuses). Other *Aspergillus* spp. are listed even though they have to date only caused infection in nonhuman mammals, such as *Aspergillus rugulovalvus* (*Emericella rugulosa*) in cattle and *Aspergillus deflectus* in dogs. Nevertheless, they have been cited in numerous texts and reviews. Exclusively nonmammalian pathogens are not listed.

PHYLUM BASIDIOMYCOTA

Each of the three classes of the Phylum Basidiomycota – Urediniomycetes, Ustilaginomycetes, and Hymenomycetes – contains species of yeasts and molds, as well as species that are capable of infecting mammalian hosts. Similar to the Ascomycota, the basidiomycetes are ubiquitous. Many are phytopathogens, such as the rusts and smuts, which are found in the Orders Uredinales and Ustilaginales, respectively. Approximately 30 000 basidiomycetous species have been described, yet only a dozen or so cause human infection (Table 6). (Toxigenic fungi, such as poisonous mushrooms, are not included in Table 6.)

The basidiomycetes are characterized by the sexual production of basidia and basidiospores. Sexual reproduction is initiated by the fusion of compatible mating partners, and a dikaryon is often formed in which each cell contains two haploid nuclei, one from each partner. This dikaryophase may be protracted, and the hyphae develop clamp connections to ensure that each cell maintains the requisite two nuclei. The clamp connections are accompanied by complex septal pores. Clamp connections are only produced by basidiomycetes, but they are not made by every member of the Basidiomycota. The signature feature of basidiomycetes is the production of basidia, which culminates the sexual cycle. The basidium is the site of karyogamy, which is followed by meiosis and mitosis, typically yielding four haploid basidiospores. The basidiospores germinate to form vegetative septate hyphae or budding yeast cells. Similar to the Ascomycota, much phenotypic and molecular evidence suggests that the Basidiomycota is monophyletic (Oberwinkler 1987; Swann and Taylor 1993, 1995b; McLaughlin et al. 1995; Prillinger et al. 2002).

Most described basidiomycetes are members of the Class Hymenomycetes, and they share the feature of distinctive, perforated, dolipore septa (Moore 1978). The largest subdivision of the Hymenomycetes is the Homobasidiomycetes, which houses mushrooms, puffballs, and other higher fungi. The classification of the higher taxa of Hymenomycetes is not completely resolved (Binder and Hibbett 2002). Another significant clade of the Hymenomycetes is the Tremellales, which contains many of the basidiomycetous yeasts (Swann and Taylor 1995a, c; Fell et al. 2000). The genera of greatest clinical importance are *Filobasidiella* (*Cryptococcus*) (Sivakumaran et al. 2003), *Malassezia* (Kano et al. 1999) *Rhodosporidium* (*Rhodotorula*), *Sporidiobolus* (*Sporobolomyces*), and *Trichosporon* (Guého et al. 1992; Sugita et al. 2002).

CLINICAL APPLICATIONS

As mentioned earlier, DNA sequences have been exploited not only to determine phylogenetic relationships but to develop molecular methods to identify cultures and detect fungal DNA in clinical material, to genotype species and strains for molecular epidemiology, and to analyze the population structure of pathogens (Taylor et al. 1999a; Burnett 2003; Xu and Mitchell 2003).

Phylogenetic studies have greatly abetted efforts to develop more accurate methods to identify species (and strains) of many pathogenic fungi. Signature DNA sequences of the target species are identified, often within the rDNA gene cluster, and specificity can be evaluated by including the closest taxa based on phylogenies of the target species (Iwen et al. 2002). PCR methods are rapid, definitive, specific, and considerably more accurate and reliable than conventional methods of identification. Increasing reports confirm the utility of PCR methods to identify isolates of dermatophytes (Kanbe et al. 2003; Shin et al. 2003), dimorphic pathogens (Walsh et al. 2003), and opportunistic molds (Kanbe et al. 2002; de Aguirre et al. 2004) and yeasts (Elie et al. 1998; Ahmad et al. 2002; Luo and Mitchell 2002; Selvarangan et al. 2003). A new commercial method, originally developed for the identification of bacteria, has proven successful in identifying fungal cultures (Hall et al. 2003, 2004). After amplifying the D2 region of the LSU rDNA of the isolate, the amplicon is then purified, cycle-sequenced, and the nucleotide sequence is compared with a database of D2 sequences of >1 000 mycotic fungi to identify the closest taxon. Multiple isolates of the same species usually exhibit <1.00 percent variation (Hall et al. 2003, 2004).

The natural next step is to develop methods to recognize and diagnose mycotic infections directly from clinical specimens, and many DNA probes and PCR

Fungal structure and morphology

PAUL F. LEHMANN

Intracellular components	1	Structures used in identification of fungi	7
Basic growth patterns: molds and yeasts	1	Conidial structure and germination	8
Dimorphism	5	Features of fungi associated with pathogenicity and virulence	10
Instability in growth pattern: 'phenotypic switching'	7	References	11

The species of the fungi that are associated with infections in humans represent a number of very different groups within the Kingdom Fungi. Three phyla of the true fungi, the Ascomycota, Basidiomycota, and Zygomycota, include infectious fungi. The remaining phylum, the Chytridiomycota, includes the order Neocallimastigales within which several genera of anaerobic fungi have been described. Anaerobic fungi have been found in the gut lumen of several herbivores but they have not been associated with human disease.

Additional organisms resemble fungi and are studied by medical mycologists. These include a pathogenic member of the genus *Pythium* (*Pythium insidiosum*), but this is a genus that is no longer included within the Kingdom Fungi being assigned, with other oomycetes, to the Stramenopiles or Kingdom Chromista (Hawksworth et al. 1995; Van de Peer et al. 2000). Another group of species, those in the *Pneumocystis carinii* complex, have traditionally been studied by parasitologists on account of their morphological similarity to some of the parasitic protozoa; however, comparative analysis of the sequences of the ribosomal RNA (rRNA) and of a number of different genes has placed this complex of species among the fungi (Cailliez et al. 1996). It is likely that several other organisms that have been treated as parasitic protozoa will be found to be fairly close relatives of fungi. Such appears to be the case for *Encephalitozoon caniculi*, a microsporidian that has emerged as a problem in immunosuppressed patients including those with the acquired immunodeficiency syndrome (AIDS) (Vivarès et al. 2002).

Most recently, the class Mesomycetozoea has been defined within the Kingdom Protozoa. This includes a number of fungus-like organisms which, based on rRNA sequences, have evolved as a lineage which is distinct from the eukaryotic kingdoms represented by fungi, animals, and plants (Mendoza et al. 2002). The Mesomycetozoea include a number of fish parasites and the human pathogen, *Rhinosporidium seeberi*, the etiologic agent of rhinosporidiosis. Relative to the fungal pathogens from the Kingdom Fungi that are the traditional study of medical mycologists, these organisms are poorly understood and, unless directly noted, will not be the subject for further discussion within this chapter.

In spite of their diversity, fungi share many features. At the simplest level, they are nonphotosynthetic, eukaryotic organisms that possess a cell wall lying external to the plasma membrane. This membrane, also known as the plasmalemma, represents the outermost cellular membrane. It is the cell wall that imparts a shape to the fungal cell and prevents it from bursting when the fungus is placed in environmental settings with low osmotic pressure. If the wall is removed, by enzymatic digestion, the cell takes on a spherical form and becomes osmotically fragile. Differential patterns of cell wall synthesis play a central role in determining both the shape of the fungal cell and the patterns of fungal growth that will be discussed herein.

INTRACELLULAR COMPONENTS

Being eukaryotic cells, all true fungi possess a nuclear pore complex within a nuclear membrane. Within the nucleus there is a nucleolus and linear chromosomes. The cytoplasm contains a cytoskeleton in which the microfilaments, which are composed largely of actin, and the tubulin-containing microtubules provide the major components (Gow and Gadd 1995). The cytoplasm also contains organelles including mitochondria, although these are not found in the anaerobic fungi, the Golgi apparatus, vacuoles, often several types of vesicle and 80S ribosomes. The plasmalemma typically contains large quantities of sterols, usually ergosterol. It is their preferential binding to ergosterol rather than cholesterol, the sterol that is dominant in human cell membranes, which explains the selectivity of the polyene antifungal agents, nystatin and amphotericin B. The pathway for synthesis of ergosterol is the target of two groups of antifungal agents. The azole antifungals, which include fluconazole, itraconazole, ketoconazole, miconazole, and voriconazole, inhibit the cytochrome P450-dependent lanosterol demethylase, while the allylamines, which include terbinafine and naftidine, inhibit squalene expoxidase.

BASIC GROWTH PATTERNS: MOLDS AND YEASTS

Fungi, not being photosynthetic, require environmental sources of fixed carbon for their growth, and two major strategies for exploiting substrata have been developed. Filamentous growth and apical extension of the filament, in association with the formation of lateral branches, are exemplified by hyphae and mycelium, while single cell division is associated with yeasts (Figure 1). Apical growth, in association with a somewhat rigid wall, allows a hypha to generate forward pressure at its tip and this, combined with the release of degradative enzymes, enables it to force its way through tissues. Branching of the hyphae leads to the production of mycelium, a large structure composed of interconnected hyphal filaments.

In contrast to the filamentous form of growth that leads to the production of a mycelium, the yeast form of growth results in the physical separation of parental and progeny cells. To exploit new sources of nutrients, yeast cells spread to more distant sites by being carried passively in moving fluids, such as in plasma, or in fluid films such as those that bathe tissue surfaces.

In addition to the basic pattern of growth by molds and yeasts, several fungi or fungus-like organisms have unusual morphologies and methods of growth. These include *Pneumocystis* where clusters of multinucleate cysts and trophozoite (single-celled) stages are seen in infected persons. In both *Coccidioides* and *Rhinosporidium*, parasitic development is characterized by the production of spherical bodies that undergo endosporulation and with the subsequently-released endospores swelling to form new spherical structures. In *Coccidioides* spp., the spherical structure (= a spherule) undergoes segmentation and fungal cell wall material divides the contents into sections in which the endospores mature. Rupture of the spherule leads to release of endospores. By contrast, the fungus-like *R. seeberi* produces a large spherical sporangium in which there is no segmentation and the endospores appear to be released through a pore in the sporangial wall (Mendoza et al. 1999). A further form of growth is seen for the parasitic stage of some etiologic agents of chromoblastomycosis: these produce sclerotic bodies showing planar division. Figures showing these forms can be seen in the appropriate chapters covering these diseases.

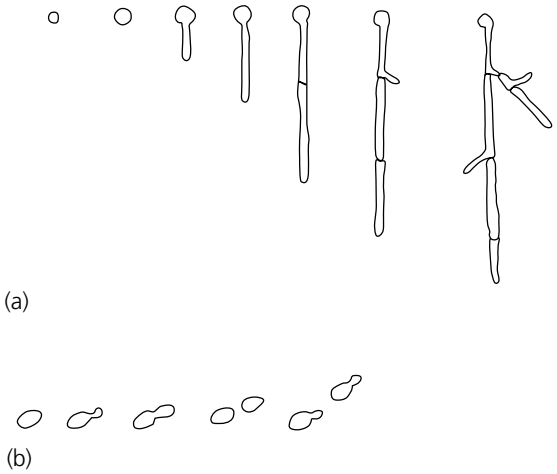

Figure 1 *Growth forms of fungi:* **(a)** *molds – the ungerminated conidium swells, then germinates to produce an apically growing hypha which develops septa and branches. Growth continues at the apices of the original hypha and branches.* **(b)** *Budding yeast cell: a common growth pattern where reproduction occurs by separation of the emerging bud from the mother cell. Both mother and daughter cells continue to bud.*

Cell wall synthesis

The actual shape of the fungal cell is determined by the cell wall. This lies exterior to the cell membrane and is composed primarily of carbohydrates, some of which are covalently linked to proteins. The cell walls of distantly related fungi can show substantial differences in their chemical composition, and so it is remarkable that hyphae of quite distantly related species may appear very similar both in morphology and in their pattern of growth. The carbohydrate components appear to be synthesized at the surface of the plasmalemma and include materials that are crystalline, such as α-glucans and chitin, which is the β(1,4)-linked polymer of *N*-acetyl-D-glucosamine. The crystalline materials are thought to provide strength and rigidity to the wall.

Other polysaccharidic components include matrix materials such as mannoproteins that may allow the wall to have some degree of flexibility. Evidence for covalent crosslinking of cell components has been found and this would be expected to strengthen the walls. Those glucan synthetases that generate β-glucans within the cell wall provide the target for the echinocandin antifungal agents such as caspofungin acetate.

The expanding hyphal tip has, at its apex, a cell wall that shows significant plasticity. Here the wall is quite thin and also is thought to be composed of materials that are more loosely associated with each other than that seen in the more mature hyphal walls where the crosslinking of the various materials appears to have been completed. For example, in contrast to the situation with mature walls, the newly synthesized chitin chains found in the tip appear not to be fully crystallized. Models for fungal cell wall synthesis have been reviewed (Sentandreu et al. 1994; Sietsma and Wessels 1994; Wessels 1994).

Hydrophobic proteins (hydrophobins) are often produced by aerial hyphae and conidia. The assembly of these molecules results in a superficial hydrophobic rodlet layer. Our understanding of these hydrophobic molecules is far from complete (Wessels 1994).

Mold growth pattern

APICAL EXTENSION OF HYPHAE

During hyphal extension, there is directed flow of precursors into the hyphal tip. Many vesicles are detectable at hyphal tips and these are considered to be the vehicles for both the enzymes and possibly some of the precursors that are required for cell wall synthesis (Heath 1994; Sentandreu et al. 1994; Sietsma and Wessels 1994; Wessels 1994; Gow and Gadd 1995). For example, some of the vesicles, termed 'chitosomes,' may carry chitin synthase in its zymogenic form. Chitosomes, when activated and incubated with UDP-*N*-acetyl-D-glucosamine, have been shown to cause the synthesis of chitin microfibrils (Bracker et al. 1976). A cluster of vesicles near growing hyphal tips can be observed by light microscopy and it appears as a distinct structure that has been named Spitzenkörper. This structure has been suggested to represent a distribution center for the vesicles migrating to the growing tips of hyphae. The Spitzenkörper is not observed when hyphal growth ceases and experimentally induced changes to its position relative to the growing tip have been linked to changes in the shape of the hyphal wall (Bartnicki-Garcia et al. 1995).

An understanding of the basic mechanisms that are involved both in maintaining the uniform cylindrical shape of a growing hypha and in producing apical extension of the hyphal tip is beginning to emerge. Multiple gene products are involved: indeed a large-scale genetic screen for mutations in *Neurospora crassa* that were associated with defects in polarized growth and hyphal morphogenesis obtained >100 complementation groups and 21 different morphological phenotypes (Seiler and Plamann 2003). Among the genes involved were those regulating the formation of the cytoskeleton or were part of the secretory pathway. Genes encoding members of the cell wall and outer membrane biosynthetic pathways and also encoding components of the signal transduction pathways, including interactive kinases, were also identified, indicating that the process of morphogenesis is complex.

The large number of morphological phenotypes and the abundance of complementation groups involved in morphogenesis enable the creation of many possible models for the control of hyphal growth. Clearly the three-dimensional form of the cytoskeleton is important; indeed, the shape may be the predominant factor that controls the shape of the cell (Heath 1994; Wessels 1994). However, a simple model is inadequate. For example, Heath has pointed out that apical growth cannot simply be explained by use of a model where turgor pressure causes tip expansion by pushing the cell contents outwards at the site where the hyphal cell wall is weakest, i.e. at the hyphal tip (Heath 1994). Among the phenomena that are not explained by that model are: the capability of cell wall mutants, for example, mutants of *Aspergillus niger* that lack chitin, to produce relatively normal looking hyphae in media of high osmotic strength, and the poor correlation between changes in internal turgor pressure and the hyphal growth rate.

As the hypha grows forward, materials are incorporated into the wall at the apex of its hyphal tip. The newly synthesized wall pushes aside the previously formed wall components that soon become part of the mature walls. In actively growing fungi, the hyphal contents do not have a uniform metabolic activity throughout the length of the hypha. Maximal activity is found at the growing tip and it is in this region that most of the absorption of nutrients appears to occur and where hydrolytic enzymes, such as lipases, polysaccharidases and proteases, are secreted. These enzymes may remain in the hyphal wall or they can be released into the surrounding substrate.

The factors controlling polar growth exhibited by hyphae have been examined for a number of different species and the subject has been reviewed fairly recently (Momany 2002). The reader is invited to obtain references to several important papers in the original literature from that review as they are beyond the scope of this introductory chapter. In spite of the difference in typical growth habit of yeasts and molds, studies have demonstrated a similarity between the central protein machinery required for the polarized growth exhibited by hyphae of filamentous fungi and the protein machinery used in maintaining polarized growth

associated with the more filamentous growth morphology of baker's yeast, *Saccharomyces cerevisiae*. This form of growth can be seen when yeast is grown on certain media. For example, a Rho-GTPase, Cdc42, drives polar growth in yeast and the homologous protein appears to perform a similar function in the ascomycetes, *Ashbya gossypii* and *Penicillium marneffei*. The function of Cdc42 appears to be to act as a target for additional proteins that themselves act as a scaffold for the cytoskeletal components (Johnson 1999). Polar growth appears dependent on the state of the plasma membrane where it has been suggested that rafts of polarity-inducing proteins may be localized. Post-translational lipid modification of some of these proteins via *N*-myristoylation (*Aspergillus nidulans*) or geranylgeranylation (*S. cerevisiae*) has been suggested as a mechanism whereby the polarity proteins develop affinity for the plasma membrane but this alone does not explain the control and maintenance of a polarized form of growth. Here, it is likely that vesicle trafficking is organized so that vesicles containing wall precursors are targeted to a single area, a process that is complex and certainly involves the correct deposition of both formins and septins. This is discussed further in the next section.

DEVELOPMENT OF MYCELIUM

Although the mature hyphal wall becomes thickened and rigid, it may still undergo modifications at a later stage. When, at some distance behind the growing hyphal apex, a small area of wall is rendered elastic, a lateral hypha can emerge as a branch (Figure 2). Typically, this new hypha grows apically and itself may give rise to lateral branches. The whole pattern leads to the development of an interconnected mycelium.

Cross-walls, known as septa, are often formed. Septa have a variety of structures with certain types being restricted to specific major divisions of the fungi, for example, septa containing dolipores are restricted to the Basidiomycota (Figure 3). The different types of septa have different effectiveness in providing barriers to the movement of nutrients, vesicles, organelles, and nuclei. Those with large pores appear to provide few restrictions. This contrasts with the control provided by septa with small or complex pores.

Septum production has been studied fairly extensively for *Aspergillus nidulans* and requires, after a conidium has germinated, that the hypha reaches a certain minimum size before a primary septum is formed. The septum develops from a cylindrical band of material that includes actin. This ring constricts so that fungal components become separated after mitosis has occurred. Septal formation is linked to mitotic events: the linkage retained as the hypha continues to grow and form new septa being at some distance behind the hyphal tip. Several proteins are involved in septal formation:

- the actins that form a ring appear to interact with the microtubules of the mitotic spindle

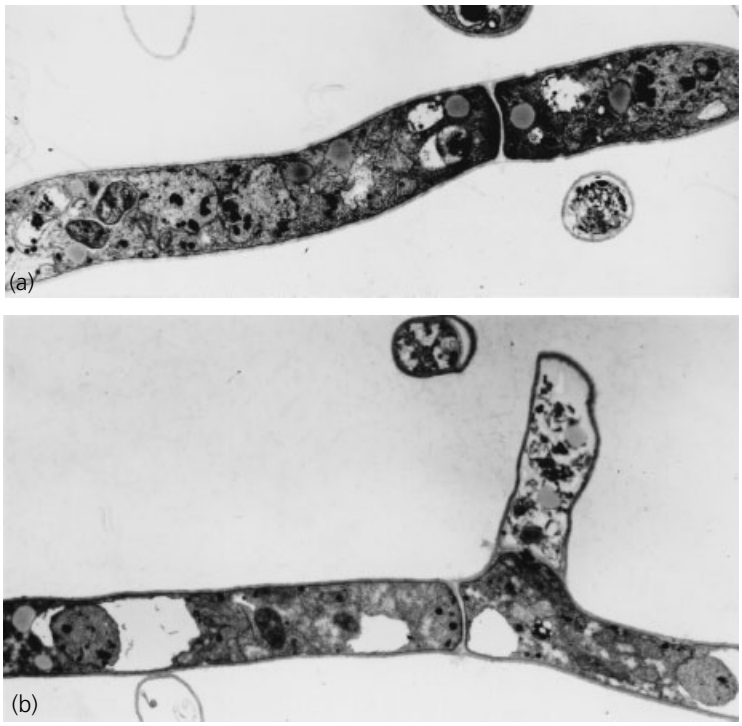

Figure 2 Coccidioides immitis *hyphae:* **(a)** *showing septum and intracellular organelles (magnification ×4 765);* **(b)** *showing formation of a branch (magnification ×6 800). Courtesy of K.R. Seshan*

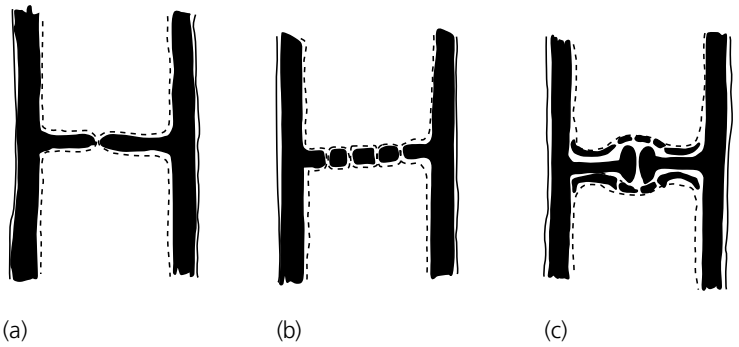

Figure 3 *Septa: there are several types. The diagramatic representations show a hyphal cross-wall developing from inward growth of the inner cell wall layers with* **(a)** *a simple pore,* **(b)** *multiple pores, and* **(c)** *a complex dolipore. In the last, the doughnut-shaped septal pore can be covered by a perforated cap.*

- the septins that belong to a conserved family of proteins found in eukaryotes where they act as morphogenetic scaffolds important in polarized growth and cell division
- the formins that seem to be needed for the correct organization of the actin cytoskeleton during cell division and the concurrent constriction of the ring of septal material.

One formin, SepA, has been detected both in the hyphal tip and at sites where septation is occurring; it appears to be required for proper deposition of the septin, AspB (Sharpless and Harris 2002). Though deposited on both sides of the constricting septum, the AspB deposited on the basal surface is not retained and disappears. By contrast, AspB is retained on the apical side of a septum and it may act as an signal or marker for cell polarity that can be exploited by the fungal cell (Harris 2001).

Some fungi, notably many species within the Zygomycota, produce few or no septa within a mycelium. Such a mycelium is essentially a coenocytic organism. There is little understanding of the molecular mechanisms accounting for polarized growth and branching of hyphae in these organisms.

The yeast pattern of growth

The pattern of growth that follows cell divisions, which result in the physical separation of daughter and parental cells, is quite different from that found for mycelial growth. Most yeasts of medical importance produce daughter cells by budding (see Figure 1). These species include *Cryptococcus neoformans*, the species of *Candida*, and the parasitic forms of several dimorphic pathogens including *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Sporothrix schenckii*. Typically, in a budding yeast, cell wall synthesis occurs over the whole surface of the bud and is not directed at a single pole. After mitosis and the migration of a nucleus into the bud, the separation of the daughter cell from the parent cell involves both the formation of a cross-wall at the site of the bud and the subsequent cleavage of this wall as the daughter cell dissociates. The wall formed at the bud site has a different structure from the rest of the yeast's cell wall and is termed the 'bud scar.' A great deal is known about the control of the growth cycle and budding in brewer's yeast, *S. cerevisiae*, which therefore acts as a model for budding yeast growth. Many of the features are conserved among species, for example, the production of a chitin-rich ring in the bud scar representing the site on the mother cell from which the daughter yeasts are cleft. But there can be significant differences in the complement of enzymes expressed by different species. Given the differences in cell wall composition associated with different species, and especially when basidiomycetous yeast species such as *Cryptococcus* are compared to ascomycetous species, it is clear that a thorough understanding of the mechanism of budding growth will require its investigation in several species.

A second form of cell division is characterized by the fission yeasts. Here the parental cell elongates and, after mitosis has occurred, the nuclei become separated by a septum that divides the elongated cell. The two daughter yeasts then dissociate after cleavage of the septum. This pattern of division is seen among few species of infectious fungi. It can be observed in the parasitic form of *Penicillium marneffei*, and also occurs in an incomplete fashion during the development of the muriform cells that are formed in vivo by the agents of chromoblastomycosis. The muriform cells are composed of cells that have reproduced by elongation and have formed a dividing septum. However, fission is delayed and further septal formation in the progeny cells can lead to somewhat irregular multicellular structures.

The basis of maintaining the growth patterns seen for budding and fission yeasts have been subject to extensive research and detailed discussion is beyond the scope of this introduction. While signal transduction via MAP kinases and other pathways such as TOR, which acts as a nutrient sensor and controls translation, are essential for allowing of growth to proceed (Crespo and

Hall 2002), it is clear that there also have to be intracellular structures that direct synthesis in an ordered manner. These structures appear to be supplied in part by polarized actin cables that, as is also seen in mycelium, are produced in a process that is dependent of formins. The actin cables act as tracks along which myosin V motors transport vesicles, organelles, and vacuolar components into the bud. The subject has been reviewed for *S. cerevisiae* by Bretscher (2003).

DIMORPHISM

Though a certain plasticity in morphology is often seen for fungi grown under different environmental conditions, several fungi associated with infections of humans can switch between the two basic growth patterns which are typified by molds and yeasts (Table 1). Indeed, the basic growth pattern of a fungus found during an infection can be quite different from that seen when it grows as a saprophyte in an external habitat such as soil. For example, *H. capsulatum* produces mycelium at environmental temperatures of less than 30°C, but reproduces as a budding yeast when growing intracellularly in patients with histoplasmosis. The capacity to switch back and forth between very distinct forms of growth is probably quite usual for fungi. Several organisms show unusual morphologies when placed at high temperature, for example, the conidia of *Aspergillus niger* can form spherical swollen cells in vitro (Anderson and Smith 1972). Such swelling is also seen in lung tissues containing the adiaspores of *Emmonsia parva*.

Table 1 *Dimorphism among selected infectious fungi*

Species	Parasitic form[a]
Agents of chromoblastomycosis[b]	Muriform cells
Blastomyces dermatitidis	Yeasts
Coccidioides immitis	Spherules
Emmonsia parva	Adiaspores[c]
Histoplasma capsulatum	Yeasts
Paracoccidioides brasiliensis	Yeasts
Penicillium marneffei	Yeasts
Sporothrix schenckii	Yeasts
Mixed growth patterns in vivo	
Malassezia furfur	Yeasts and short hyphae[d]
Candida spp.[e]	Yeasts, pseudohyphae, hyphae and chlamydoconidia[f]

a) Characteristic form seen during active infection.
b) In several examples of chromoblastomycosis a mixture of structures may be seen. In some cases, the dominant morphology may depend in part on the host immune reactivity.
c) These represent swollen spores and do not replicate.
d) This yeast species, which requires lipid for growth, generally does not produce filaments when cultured on conventional media.
e) There is substantial variability among the species. Some *Candida* spp., for example *C. (Torulopsis) glabrata*, grow only in the yeast form. Some others produce a mixture of yeasts and pseudohyphae, yet do not appear to produce true hyphae.
f) Among *Candida* spp., only *C. albicans* is known to produce chlamydoconidia in vivo. Structures that probably represent these conidia have been detected in experimentally infected mice (see text).

The reversible modification of growth pattern in response to environmental changes results from modifications affecting both the components of the cell wall and the pattern in which cellular components are deposited. This capacity to switch the pattern of growth in response to an environmental change has been termed 'dimorphism.' The same term has also been applied to describe situations where a multiplicity of growth forms can be produced by making adjustments to the conditions under which a species is cultivated. The signal for a switch in morphology from the saprophytic form to the parasitic form can, in many cases, be shown to follow an elevation in environmental temperature. However, adequate nutrients must also be present: for example, the switch to the parasitic yeast form by *H. capsulatum*, which is achieved by transferring a culture from room temperature to 37°C, is inhibited if cysteine is not included within the culture medium. Nutritional changes and elevations in P_{CO_2} can be required to induce changes in the growth patterns of *Coccidioides immitis*. For *Candida albicans*, several seemingly independent environmental stimuli may enhance a switch between yeast and filamentous growth patterns (Berman and Sudbery 2002).

A number of species are known that produce a variety of growth patterns even while causing infection. *Malassezia furfur*, an obligatorily lipophilic yeast, produces both budding yeast and short hyphae on the skin surface. *C. albicans* and a number of other *Candida* spp. grow both as budding yeasts and in filamentous forms. Indeed, in a single lesion caused by *C. albicans*, one may see histological evidence for yeast cells, hyphae, and pseudohyphae (Figure 4). In addition to its growth in filamentous forms and as a yeast, *C. albicans* is also known to produce chlamydoconidia. These spherical conidia, having thick cell walls, are easily seen when the species is cultivated on yeast morphology agars such as rice extract agar. Although similar conidia have been seen in sputum from an AIDS patient, and can be detected by use of differential cell wall staining and electron microscopy in submucosal tissues of immunosuppressed mice after experimental intragastric infection with *C. albicans* (Chabasse et al. 1988; Cole et al. 1991), it is remarkable that chlamydospores are hardly ever reported from clinical specimens. The *C. albicans* chlamydoconidium may be a resting structure and may not actually represent a replicative form.

With the recent sequencing of the *C. albicans* genome (www-sequence.stanford.edu/group/candida/search.html), it has been possible to identify many genes that appear to be homologous to ones previously investigated in *S. cerevisiae*. The expression of the genes involved in morphogenesis can change quite substantially during dimorphic growth and this is discussed in a recent review

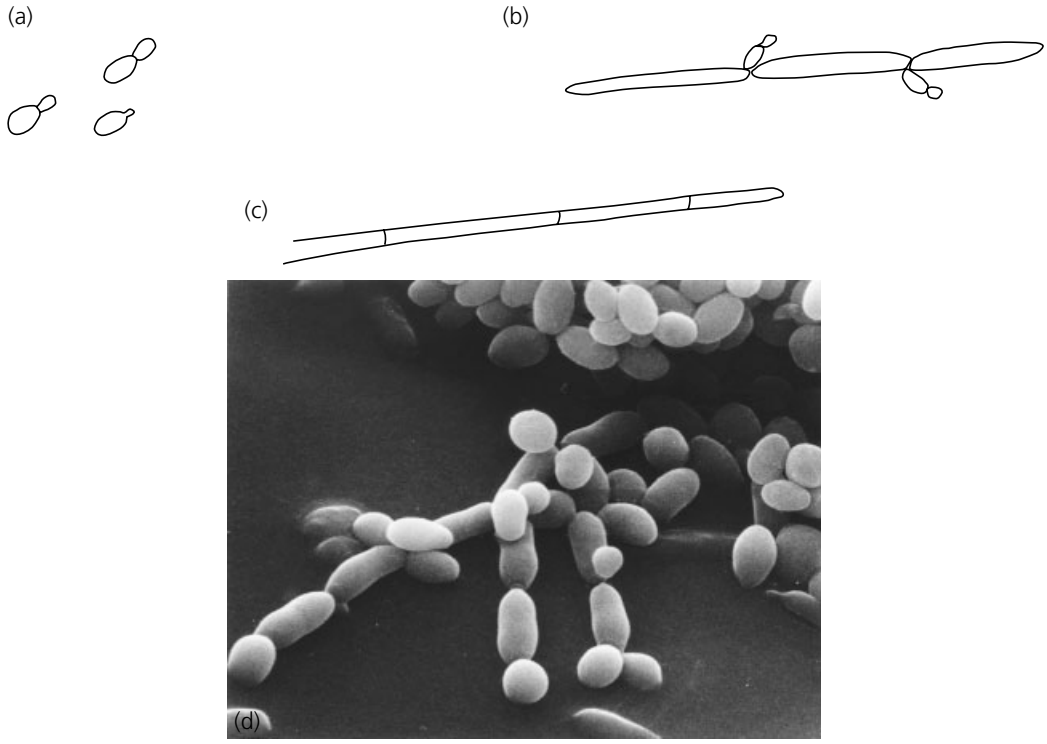

Figure 4 *The diagramatic representation shows morphological types of the yeast* Candida albicans. **(a)** *Yeast cells;* **(b)** *pseudohyphae and yeast cells;* **(c)** *a hypha;* **(d)** *budding yeast cells and pseudohyphae of* Candida kefyr *(magnification ×2 520). Courtesy of G.T. Cole*

which includes photomicrographs indicating how septin is deposited in a different fashion in the various morphological forms of *C. albicans*, i.e. budding yeast, hyphae, and pseudohyphae (Berman and Sudbery 2002). The pseudohyphal rather than the hyphal form of *C. albicans* appears to show most similarity with the 'filamentous' form of *S. cerevisiae*. At least four major signal transduction pathways appear involved in controlling the switch from yeast to filamentous forms of *C. albicans*.

Typically, *Candida* spp. grow as yeasts in media containing abundant glucose and oxygen, and isolates of many of these species can produce filamentous extensions when placed in conditions where the PCO_2 is raised and the glucose concentration is reduced. Such conditions are associated with growth under coverslips on cornmeal agar and in media used to test for germ-tube production by *C. albicans*. Other yeast species, such as *Candida glabrata*, a species which is more closely related to *S. cerevisiae* than to *C. albicans*, show no evidence for this capacity and, until recently, were widely considered to be species having no capacity to form filaments. However, as already alluded to above, research with *S. cerevisiae* has elucidated nutrient conditions that can induce polar cell growth causing production of pseudohyphae (Gimeno et al. 1993). Thus, even in species where there has been little evidence of dimorphism, there may exist an unexpected flexibility in growth pattern. Indeed, the haploid pathogenic basidiomycetous yeast species, *Cryptococcus neoformans*, can be induced to grow in a filamentous fashion when cultivated under conditions that differ from the standard glucose-rich media used in Sabouraud's agar or other media that are typically used when cultivating fungi in the clinical laboratory (Wickes et al. 1996). Before this discovery, a filamentous morphology had only been known for the teleomorph produced when two haploid strains mate.

Although it seems likely that a capacity to produce filamentous growth patterns will be found for many other yeasts that previously have not been considered dimorphic, it remains to be proven that the filamentous growth, seen only on certain media, plays any significant role in the establishment and pathogenesis of infections caused by either *Cryptococcus neoformans* or *S. cerevisiae*. By contrast, the yeast and filamentous forms of *C. albicans* behave so differently that it is likely that dimorphism is essential for maximal virulence. For example, they show different capacities for binding to epithelial cells and to several host proteins including complement components: such variability likely enables the fungus to colonize, grow, and become released from a variety of niches. The report that a mutant lacking mitochondrial NADH dehydrogenase complex I fails to develop filaments, though it grows normally as a yeast, suggests that energy demands for yeast and filamentous growth could be rather different with the hyphal form requiring relatively high production of ATP and

reducing power (McDonough et al. 2002). While differences in the metabolic state of cells might contribute to the induction of morphological variability, including white–opaque switching (next section), environmental cues are important for inducing the morphological switch as culture media containing very similar nutrients can support both types of growth. The morphological flexibility of *C. albicans* is so notable in that it is extremely rare to find clinical lesions where only one morphological form exists and, indeed in biofilms formed on plastic appliances, both forms are observed (Chandra et al. 2001).

INSTABILITY IN GROWTH PATTERN: 'PHENOTYPIC SWITCHING'

In addition to the changes in growth patterns associated with dimorphism, an additional form of morphological flexibility has been described whereby, at least in culture, certain species undergo 'phenotypic switching.' This process, first described for certain strains of *C. albicans*, differs from dimorphism in that the changes in growth form appear spontaneously, usually at a rate of between 1:1 000 and 1:10 000 progeny cells, (Slutsky et al. 1985). The different patterns of growth result in the generation of differently shaped colonies when these are cultivated on agar media. Most progeny colonies from a single colony type retain the growth pattern of the parental colony; however, some colonies develop where the pattern appears to have switched to one of a number of alternative phenotypes (Figure 5). It appears that phenotypic switching increases the capability of *C. albicans* to adapt to different environments and environmental stresses for switches of metabolic activity may also be found. Features of the switching process, including its relevance to pathogenesis, have been reviewed (Soll 1993).

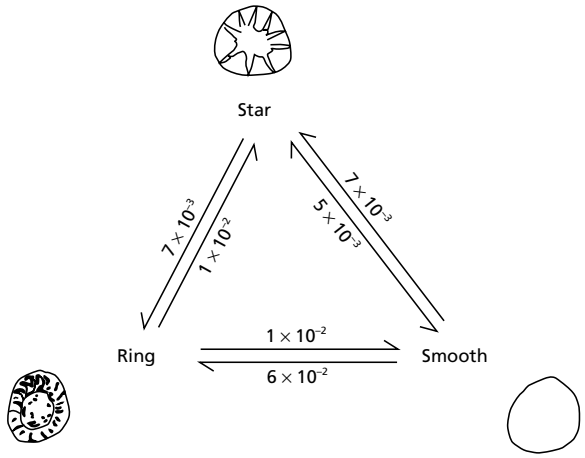

Figure 5 *Phenotypic switching in* Candida albicans. *Switching rates from one colony phenotype to another are examples taken from data showing switching between several distinctive colony phenotypes that were reported by Slutsky et al. (1985).*

A second phenotypic switching system, the white–opaque system, has been described and the regulation of genes expressed in each form has been investigated by using a microarray of *C. albicans* genes (Lan et al. 2002). There were substantial changes not only in the expression of genes that are likely to interact directly with the host, but also in the general metabolic activities of the yeasts in these two phases. In addition, there was an upregulation of the expression of mating type-associated genes in the opaque phenotype. This latter property correlates well with the recent discovery that the opaque cell type can undergo efficient mating (Miller and Johnson 2002), a feature that is not seen for the regular 'white' phenotype which is characterized by having a heterozygous mating type locus (*MTL***a**/**α**). In contrast, the mating type locus found in the opaque phenotype is homozygous (*MTL***a**/**a** or *MTL*α/α). This novel finding suggests a process by which gene flow can occur fairly easily in populations of *C. albicans*.

Phenotypic switching is now reported for several other fungal pathogens of humans including *Candida parapsilosis* and *Candida tropicalis*, which are both closely related to *C. albicans*, and for more distant species including *C. glabrata*, a species that is more closely related to *Saccharomyces*, and the basidiomycetous yeast *Cryptococcus neoformans* (cited in Soll et al. 2003). It has been clearly linked to pathogenicity in *C. albicans* and it is very likely to found in several other organisms, including plant pathogens and non-pathogens, which can exist in highly variable environmental niches where the switching may be coordinated by changes in the activity of global regulators controlling the expression of families of genes. Further insights into the signaling process leading to phenotypic switching could identify useful targets of antifungal chemotherapy.

STRUCTURES USED IN IDENTIFICATION OF FUNGI

Although there have been substantial advances in the use of molecular characteristics, such as antigens and nucleic acid sequences, for the identification of fungal pathogens, the morphological features of fungi still play a dominant role in allowing microbiologists to identify filamentous fungi. By far the most important taxonomic characters are those associated with the morphology of spores and fungal structures on or within which the spores are produced. With molds, spore-bearing hyphae typically grow aerially in a manner that raises the spores away from the vegetative hyphae. A substantial number of differential characteristics are associated with these specialized hyphae and the spores they bear, and these allow isolates to be identified both to genus and, very often, to species level. The vegetative hyphae, by contrast, tend to be fairly simple and show few characteristics that allow different species to be discriminated. However, certain hyphal features, including

pigmentation, size, and the type and abundance of the septa, may be helpful in eliminating particular species as choices in the identification of an unknown mold.

Many fungal propagules may be produced in an asexual process whereby their production does not require prior fusion of nuclei and a subsequent meiosis. Sporulating colonies that bear such conidia are known as anamorphs and, because more than one form of conidium may be produced by some fungi, there are examples where a single species can produce more than one anamorph. The sporulating structures that are associated with sexual spores that are produced after meiosis has occurred are named teleomorphs. The terms anamorph and teleomorph are also known as the imperfect and perfect states, and both are separately classified and named for a genus and species. As a single organism may produce both anamorphs and teleomorphs, many fungi have more than one name. It is important to realize that the different names do not describe different organisms; rather they describe different reproductive types. One sees a parallel among humans where a change of name does not alter the identity of the person.

The reason that more than one name is used for a fungus is largely based on practicality. Most fungi are heterothallic, i.e. they have mating types that ensure outbreeding, and for these species the production of teleomorphs requires the mating of different strains. As most clinical isolates involve a single strain, it would be necessary to employ a battery of tester strains were we to try to identify each anamorph via the production of its teleomorph. Not only is this inconvenient compared with naming a fungus on the basis of its anamorph, but conditions for obtaining teleomorphs have not been found for many important pathogenic species, for example *Aspergillus fumigatus* and *Coccidioides immitis*. Even when a teleomorph is known, the anamorphic form may have been studied for many decades before the discovery of the perfect state. Such situations exist for many important pathogens that are primarily known by the name given to their anamorphs. Such species include *B. dermatitidis*, *H. capsulatum*, *Cryptococcus neoformans*, and many species of dermatophytes within the genera *Trichophyton* and *Microsporum*. Imposition of nomenclature based on teleomorphs, for these examples *Ajellomyces dermatitidis*, *Ajellomyces capsulatus*, *Filobasidiella neoformans*, and species of *Arthroderma*, would be very confusing for most physicians and clinical microbiologists.

The major groups of anamorphic sporulation structures associated with infectious fungi are illustrated in Figures 6, 7 and 8. There are two major groups of asexual propagules. Those propagules that are produced as naked, asexual, nonmotile propagules, and which usually fall away from the parent hypha or yeast, are known as conidia. The specialized hypha on which they are formed is termed a 'conidiophore.' There are two basic ways that conidia are produced. Blastoconidia differentiate after ballooning out of a fertile hypha and are characterized by developing a conidial wall that is produced *de novo* (Figure 6). By contrast, those conidia that are produced via thallic conidiogenesis (Figure 7) develop from a preexisting hypha where modification of the cell wall and the cell contents leads to the development of the conidium (Cole and Samson 1979).

The second major form of asexual sporulation involves the production of sporangiospores (Figure 8). These asexual spores are only produced by fungi within the phylum Zygomycota. The most common form of sporangiospore production is associated with the multispored sporangium which has the appearance of a swollen vesicle produced on the end of a specialized hypha, the sporangiophore. Within the sporangium the spores are formed after nuclear divisions and cytoplasmic cleavage have taken place. After this, new spore walls are synthesized and these surround the spore initials (Cole and Samson 1979). Once the sporangiospores are mature, the sporangial wall breaks open to allow their release. In species that produce sporangiola, such as those within the genus *Cunninghamella*, the spores are pushed out of the swollen ends of the branches produced by the sporangiophore and the spore wall becomes fused to the sporangial wall. At first sight the sporangiola can resemble conidiophores that bear blastoconidia, but their pattern of spore development is quite different (Cole and Samson 1979).

Current taxonomic studies are increasingly becoming dependent on molecular genetic analysis, especially with the introduction of several allied organisms including agents of the Mesomycetozoea that were discussed in the introduction to this chapter. However, within the true fungi, the study of teleomorphs has been most useful in clarifying the systematic position of many anamorphic fungi and yeasts. For any one species, one type of spore is produced by the teleomorph. Species from within the phyla Ascomycota, Basidiomycota, and Zygomycota produce, respectively, ascospores, basidiospores, and zygospores.

Spores produced by teleomorphs appear rarely to be involved with human infections although their infectious potential has seldom been studied. However, there are certain situations where the sexually derived spores appear important. In black piedra, the asci and ascospores of *Piedraia hortae* are found in the nodules that develop on infected hairs. Also, basidiospores are the most likely source of infection in the few cases of invasive disease that have been reported for the mushrooms, *Schizophyllum commune* and *Coprinus cinereus*.

CONIDIAL STRUCTURE AND GERMINATION

Asexual propagules produced by the infectious fungi are the form of the fungus responsible for establishing most human infections, especially those infections that follow pulmonary exposure. Fungal conidia also play an

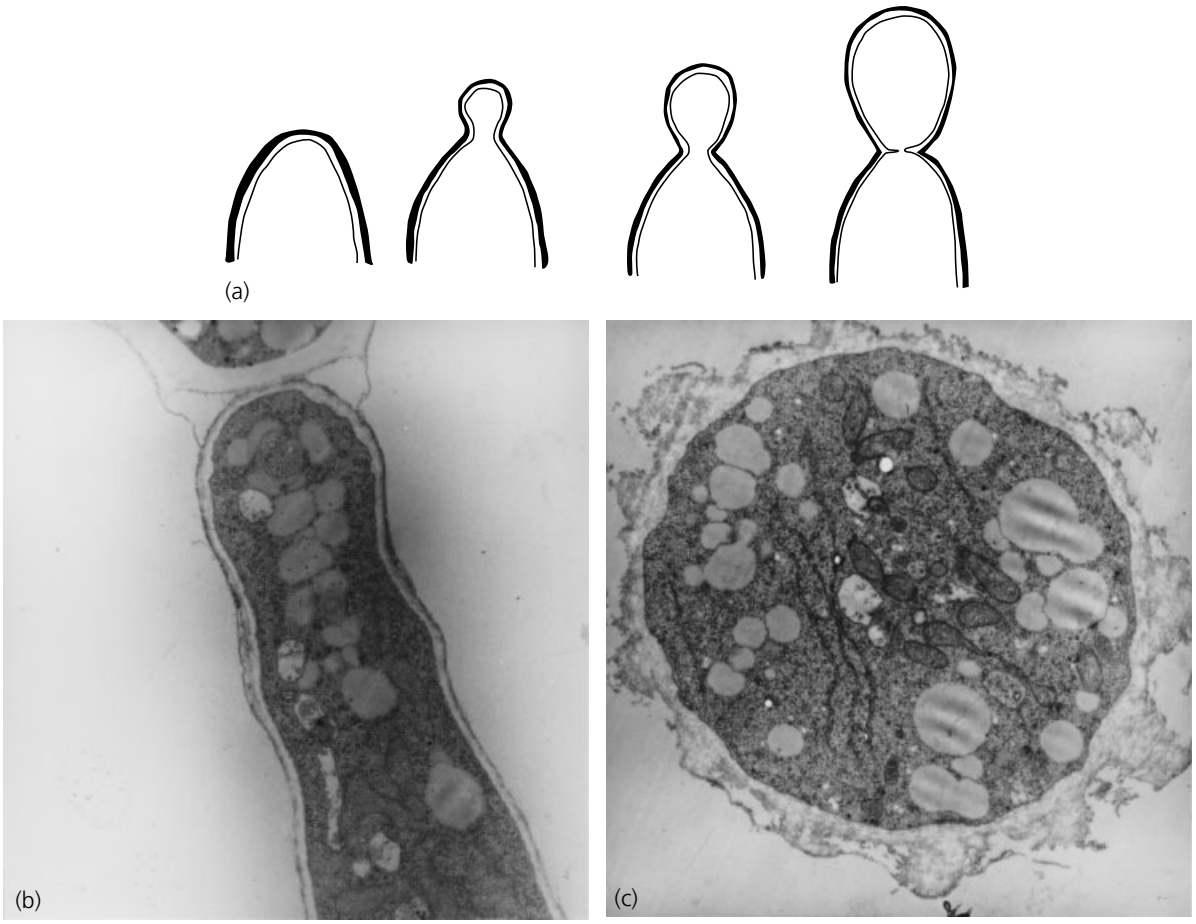

Figure 6 (a) *Conidiospore development by blastic conidiogenesis where the conidium is pushed out of a conidiophore and its cell forms newly synthesized cell wall material. The inward growth of the inner wall seals the area of emergence.* **(b)** Scopulariopsis brevicaulis *conidiophore (magnification ×11 000) and* **(c)** *mature conidium (magnification ×14 350). Courtesy of G.T. Cole*

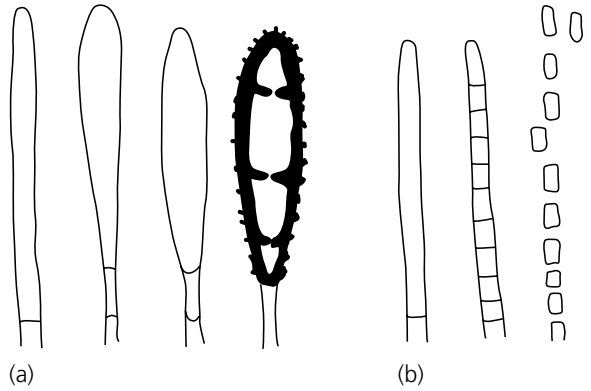
important role as allergens and may carry mycotoxins. Although the sexual reproductive process has been studied extensively because of its importance in identification, the biological activities of the fungal propagules produced by pathogens of humans have not received the same scrutiny.

It is clear that the conidium's cell wall can show quite different surface features to the walls of vegetative cells. In many cases it can be quite hydrophobic. The components responsible for the hydrophobicity appear in the form of sheets of rodlets that have been named 'rodlet fascicles.' These, depending on the species and strain, can be extracted from the conidial surface by use of water and detergents (Cole and Samson 1984; Sietsma and Wessels 1994). The hydrophobic rodlet material resembles the hydrophobins that are found in mushroom fruiting bodies, but the latter require more powerful solubilization techniques, such as the use of trifluoroacetic acid (Lugones et al. 1996).

Conidia germinate by producing germ tubes that represent hyphal outgrowths. Regardless of conidium type, the germination process usually requires the presence of CO_2, oxygen, and water for activation to occur. In many cases, exogenous low molecular weight nutrients may also be required. When conidial germination inhibitors are present in the conidia, they can be leached into the surrounding liquid and their dilution allows the conidium to begin to germinate. Germination is associated with the swelling of the conidium where water is taken up and the wall begins to expand. At the same time, there is a marked increase in metabolic activity that is observable before the emergence of the germ tube. When cell wall deposition becomes polarized, the germ tube forms. Though much research has been done on factors influencing the germination of spores, there have been relatively few studies on the molecular controls of the process in different fungi. Spores often contain large quantities of trehalose, a disaccharide that is hydrolyzed to glucose by spore-associated trehalases. These may require activation during germination or, if in a separate cellular compartment such as the cell wall, may be brought into contact with trehalose when the spore swells (D'Enfert 1997).

Germination signals can vary for different species and for different conidial types produced by a single species. For example, the arthroconidia of *Trichophyton*



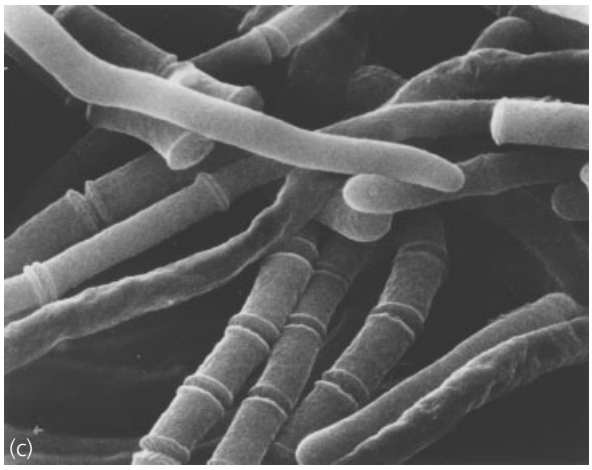


Figure 7 *Conidiospore development by thallic conidiogenesis where a conidium forms after remodeling of existing hyphal walls.* **(a)** *Development of an aleuriconidium after swelling, septation, and ornamentation of a hypha.* **(b)** *Development of arthroconidia after formation of cross-walls that allow disarticulation of the hypha.* **(c)** *Hyphae and arthroconidia formed by a species of* Trichosporon *(magnification ×1 680). Figure 8 *Sporangiospore development: spores form after division of nuclei and cleavage of the cytoplasm which accumulates within the swollen tip of the sporangiophore. Mature sporangiospores are formed within a sac (the sporangium) and are released when this ruptures.*

mentagrophytes germinate after being 'activated' by either a short exposure to elevated temperature (45°C, 10 minutes), or by soaking in water at room temperature for 24 hours. After this pretreatment, the conidia germinate in the absence of exogenous nutrients, producing germ tubes when held in water at 37°C. By contrast, the microconidia of *T. mentagrophytes* do not germinate in the absence of exogenous amino acids or dipeptides. Such differences in germination requirements may well explain the poor infectivity of microconidia when compared to arthroconidia produced by the same dermatophyte (Hashimoto 1991).

FEATURES OF FUNGI ASSOCIATED WITH PATHOGENICITY AND VIRULENCE

Much has been written concerning those characteristics of pathogens that contribute to their virulence. Certain properties are necessary for effective pathogenicity, for example, tolerance of body temperatures and ability to grow using the nutrients available in tissues. But a successful pathogen must also be able to establish an infection, a process that not only involves ensuring that the host is exposed to infectious propagules but also that, once exposed, the propagules can survive and grow in the face of a mobilized host defense. In the case of the pathogens that infect via the lungs, spore size can be of great importance. For example, the conidia of *Aspergillus fumigatus* are small enough to enter the alveoli, a feature that is not the case for all aspergilli.

There is a significant body of work demonstrating the importance of the antiphagocytic capsule to the virulence of *Cryptococcus neoformans*. But other features, such as the production of phenoloxidase (a laccase), can play a role in virulence when this species invades the central nervous system. The features associated with virulence are considered in the chapters concerning the different fungi.

Normal cellular processes such as the signal-transduction cascades, exemplified by the MAP kinases, have been found to be necessary for normal development and virulence in *C. albicans* and *Cryptococcus neoformans*. The specificity of pathway selection and activation during host–parasite interactions is an area of active research and it seems likely that at least some of these signals induce the production of virulence factors by pathogens (Lengeler et al. 2000). However, this may not turn out to be the case for many of those opportunistic fungi that are saprophytes and are very unusually seen as pathogens in humans or animals. In a similar fashion to the situation with signal transduction pathways, certain steps in metabolic pathways may need to be present for effective pathogenicity. Auxotrophic mutants can have greatly diminished virulence, a feature reported for *Aspergillus nidulans* (Purnell 1973), *Cryptococcus neoformans* (Perfect et al. 1993), and *C. albicans* (Guo and Bhattacharjee 2003). While such 'normal'

processes may not play a central role in host–parasite interactions, they might well provide useful targets for antifungal drugs.

Evidence of fungal components being important in virulence has been sought by using molecular genetic methods. Typically, a protein that is thought to be important in virulence may be inactivated, usually by generating a mutant. The most efficient way to generate targeted mutations where reversion does not occur has been to disrupt the gene encoding the target protein. After gene disruption and demonstration that the protein is no longer expressed, the significance of the protein may be estimated by comparing the virulence of the mutant to the original wild-type. Should the mutant show reduced virulence, it is then essential to show that it regains virulence when a functional target gene is reinserted. What has become clear is that most fungi appear to exploit numerous components for virulence and that simple disruption of one gene may not have much obvious effect when there are several genes encoding a particular activity, for example with serine proteinases or chitin synthetases. In some cases, gene disruption shows significant effects on certain stages in the infectious process: for example phospholipase B1 mutants of *C. albicans* retain some pathogenicity but have reduced invasive capacity (Ghannoum 2000). Details of current knowledge on fungal virulence factors are beyond the scope of this introductory chapter.

GENERAL STATEMENT

The diagnosis of a fungal disease is a complicated event requiring the cooperation and collaboration of many people with diverse expertise. Most fungal diseases require a laboratory diagnosis, so it is imperative that the laboratory is in close communication with the physician. This is especially important with the dramatic changes in potential hosts for fungal diseases in this era of immunosuppression and transplantation. As the host has changed, so has the range of potentially 'pathogenic' fungi. It is now well documented that many fungi in the environment may cause disease in severely compromised human hosts. The physician and laboratorian must thus be prepared to consider any fungal isolate as being etiologically significant and take appropriate measures to incriminate or disprove its role in each patient's case. The most commonly used methods for the laboratory diagnosis of fungal infections are, in general, old and time-honored. The recovery of the etiologic agent from clinical specimens is still considered to be the 'gold standard.' Methods used for identification of the fungi are a mixture of traditional and newer commercially available systems, e.g. yeast identification kits. Molecular methods are being developed for the detection and identification of fungi at a very fast rate; however, no comparative studies have been done to determine which are optimal and no standards for testing have been developed to date. Molecular testing is the future for many areas of clinical mycology but it will be some time before routine testing will be standard practice within the laboratory. A section at the end of this chapter will present a preview of what has been done and some insight in to what will be useful in the future.

SPECIMEN SELECTION

The laboratory diagnosis of a fungal disease starts with careful collection of the appropriate clinical specimen. The specimen must contain the viable etiologic agent, if it is to be recovered and identified. The anatomic site in which the organism is present must be carefully selected and the specimen collected in such a manner that it will allow the fungus to remain viable in its 'natural' state, without contamination (Merz and Roberts 2003). Sites from which to collect specimens for the most common mycoses are given in Table 1.

When the appropriate site is selected, the specimen should be placed in a suitable container and promptly sent to the laboratory.

SPECIMEN COLLECTION

Specimens that are inappropriately collected, stored, or not processed on time may cause misdiagnoses, delays in appropriate therapy and increased costs for the patient.

The following are guidelines for specimen collection:

- Collect the specimen from an active lesion; old 'burned-out' lesions often do not contain viable organisms.

Table 1 *Selection of clinical specimens for fungal culture: order of preference for site selection*[a]

Specimen	Blastomycosis	Coccidioidomycosis	Histoplasmosis	Paracoccidioidomycosis	Candidiasis	Cryptococcosis	Aspergillosis	Zygomycosis	Hyalohyphomycosis	Dermatophytosis	Chromoblastomycosis	Pheohyphomycosis	Sporotrichosis	Mycetoma
Lower respiratory tract	1	1	1	2	x	1	1	1	3	–	–	–	3	–
Blood	–	6	2	–	1	2	–	–	2	–	–	–	x	–
Bone	4	x	–	x	–	x	x	x	–	–	–	–	x	–
Bone marrow		x	3	x	x	x	–	–	x	–	–	–	–	–
Brain	x	x	–	x	x	x	x	3	x	–	x	2	–	–
Cerebrospinal fluid	x	x	x	–	x	5	–	–	–	–	–	–	x	–
Eye	–	–	x	–	x	–	x	x	5	–	–	–	–	–

Multiple systemic sites during disseminated infection	6	4	6	4	3	4	3	5	6	–	x	–	x	–

a) Predominant sites for recovery of organism are ranked in order of importance (based on most common clinical presentations). x indicates other sites from which organisms have been recovered.

- Collect the specimen under aseptic conditions.
- Collect a sufficient amount of the specimen.
- Collect specimens before instituting therapy.
- Use sterile collection devices and containers.
- Label the specimens appropriately; all clinical specimens should be considered as potential biohazards and should be handled with care using universal precautions.

Respiratory tract specimens

The most common specimen for the diagnosis of fungal pneumonia and chronic pulmonary disease is sputum. The best specimen can be obtained when the patient first awakens from sleep, after the oral cavity has been cleansed. Bronchial alveolar lavage (BAL) and bronchial brushings are usually superior to sputum, provided that double- or triple-lumen bronchoscopes are used to prevent upper respiratory microbial contamination. Well-collected lower respiratory specimens are very useful for direct microscopic observation and culture for fungi.

Sterile body fluids (cerebrospinal, peritoneal, pericardial, synovial and vitreous humor)

These provide excellent specimens because there are usually no contaminating organisms present. Sterile fluids should be obtained under aseptic conditions using a sterile syringe. The specimen should be transferred to a sterile, closed tube for transport to the laboratory. Small amounts of fluid can be transported in the syringe, after the needle has been removed and the syringe re-capped.

Tissue

Tissue from the site of active disease process is the ideal specimen for diagnosing a mycosis and it should be collected under strict aseptic conditions. It should be placed into a sterile, closed container of the appropriate size. An adequate volume of sterile saline, without preservative, should be added to the container to keep the tissue moist. If the tissue cannot be processed immediately, it may be refrigerated, but not frozen, before it is examined microscopically and cultured.

Exudates/pus

Specimens from closed lesions and abscesses are usually of high quality. The outer surface of the site should be thoroughly cleansed and decontaminated. The specimen should then be aspirated with a syringe and needle and transferred to a sterile, closed container. Swabs should never be used to collect a specimen from a closed lesion that has been surgically opened. Drainage from open lesions should be collected only after the lesion has been thoroughly cleansed. Care should be taken to collect any granules that may be present in specimens from open or closed lesions. If swabs must be used to collect a specimen from an open lesion, a maximum amount of material should be collected on the swab and kept moist *en route* to the laboratory.

External eye

Corneal scrapings should ideally be placed directly on to the surface of fungal culture media and on to the center of a clean, glass microscope slide to be used for direct microscopic examination. Fluid from an eye should be aspirated with a sterile syringe and needle and, if only a small quantity is present, transported to the laboratory in the syringe. Quantities greater than 0.5 ml should be transferred to a sterile tube for transport to the laboratory (Jones et al. 1981).

Urine

Urine specimens (50–200 ml) should be placed in a sterile, screw-capped container. Urine specimens should be freshly collected. Specimens from catheter bags are unacceptable. Urine may be refrigerated if it cannot be cultured promptly.

Blood

Blood should be collected under strict aseptic conditions. The specimen may be collected directly into a culture system or with a syringe, and then transferred to an appropriate culture medium. Strict aseptic conditions must be maintained in all situations (see section on Blood cultures below for more details).

Stool

Under very special circumstances, fecal cultures for fungi are appropriate, e.g. profoundly immunosuppressed bone marrow transplant recipients. The specimen should be collected in a sterile, screw-capped container or on two rectal swabs.

Hair

Infected hair should be drawn from the scalp with forceps and placed into a clean, dry container. Clipped hair is not acceptable because the root is the prime specimen. It is not necessary to use a sterile container. Hair for culture should be free of topical medications, conditioners or dressings.

Skin

Specimens of skin may be obtained by scraping or biopsy. A site on the active border of the lesions should be used. As skin is usually contaminated with other microorganisms, the surface of the selected site should be cleansed with 70 percent isopropyl alcohol. The epidermis should be scraped with a scalpel or other instrument and the scrapings placed in a clean, dry container, such as a Petri dish, specimen cup or envelope. Biopsied specimens should be placed in a sterile container.

Nails

Nails should be cleansed with 70 percent alcohol. A portion of the infected nail should be clipped and the excess keratin scraped from the nail bed. The clippings and scrapings should then be placed in a clean, dry container.

SPECIMEN TRANSPORT AND STORAGE

For best results, all clinical specimens should be microscopically examined and cultured as soon as possible. Except for blood and corneal scrapings, it is not necessary to transport the specimen in a transport medium. Blood should be placed in the preferred culture system or the lysis centrifugation system (Isolator, Carter Wallace Wampole Laboratories, Cranbury, NJ, USA). Corneal scrapings should be inoculated onto the medium when collected. Specimens should not be frozen before culture. Specimens not likely to contain contaminating microorganisms, e.g. spinal fluid, and those that could contain dermatophytes should not be refrigerated. Transported specimens should never be allowed to dry out. Sputum specimens may be transported without preservation if only dimorphic fungi are to be recovered (Hariri et al. 1982).

SPECIMEN PROCESSING

When specimens reach the laboratory, they must be appropriately processed to ensure viability of the etiologic agent and to minimize the chances of contamination. Specimens from normally sterile sites, e.g. spinal and peritoneal fluids, need no special processing, but may be cultured directly onto primary recovery media. If the volume is adequate, specimens should be concentrated by centrifugation membrane filtration, and the concentrated specimen aseptically transferred to primary recovery media for culture and on to a clean microscope slide for direct microscopic examination. Aseptically collected tissue should be homogenized in a tissue grinder, mortar pestle or 'stomacher.' A portion of tissue suspected to contain a zygomycete should be finely minced with a pair of scissors or scalpel.

A highly viscous specimen, such as sputum, should be liquefied before culture, but it should not be excessively diluted. It should be concentrated by centrifugation if it is too dilute.

CULTURE

Most of the mycotic diseases are diagnosed by recovering and identifying the etiologic agent in the clinical laboratory. Few fungal diseases can be diagnosed clinically. The recovery of fungi from a clinical specimen begins with the selection of appropriate primary culture media that must include one that will support the growth of any potentially pathogenic fungus in the specimen and others that will selectively inhibit contaminating microorganisms. These media must be selected with great care; however, a number of options are available.

Media

Fungi may be recovered on most bacteriological media if given enough time to grow. There are, however, well-established fungal culture media, that are optimal for the recovery of fungi from clinical specimens. The following are some of the most commonly used media for recovering fungi from clinical specimens: Sabouraud's dextrose agar; Emmons' modified Sabouraud's agar; brain–heart infusion (BHI) agar (with or without 5 percent sheep red blood cells), Sabouraud's brain–heart infusion (SBHI) agar; inhibitory mold agar (IMA); mycosel or mycobiotic agars; potato flake agar; and yeast extract phosphate agar.

Combinations of antibacterial antibiotics and cycloheximide may be added to these media to make them selective. Suggested uses for these media are presented in Table 2 and, as indicated, a battery of different media should be used to culture specimens when more than one organism is expected to be recovered.

As in all areas of microbiology, the key to rapid and accurate identification of an organism is a pure culture. Isolated colonies are needed for morphological or biochemical identification. It is, therefore, necessary to spread specimens suspected of containing multiple organisms on to a large surface area. Petri dishes are generally optimal but others, such as tissue culture flasks or large bottles, are adequate. Standard, microbiological, culture tubes should not be used because colonies cannot be easily isolated from fluid specimens such as sputum and urine.

Incubation conditions

Fungi commonly associated with disease will grow well at temperatures between 25°C and 30°C. It is generally accepted that 30°C is the optimal temperature for

Table 2 *Media useful for the recovery of fungi from clinical specimens*

Specimen	Inhibitory media (bacteria and/or saprobic fungi)[a] with 5% sheep blood	Inhibitory media (bacteria and/or saprobic fungi)[b]	Yeast extract–phosphate agar
Lower respiratory tract	x	x	x
Secretions (e.g. sputum)	x	x	x
Tissue (lung or pleura)	x	x	–
Bone marrow	x	x	–
CSF	x	x	–
Eye	–	x	–
Nares/nasal sinuses	x	x	–
Skin/mucous membrane lesions	x	x	–
Tissue biopsy (not contaminated)	x	x	–
Contamination suspected	x	x	–
Urine	x	x	–

a) Includes brain–heart infusion (BHI) agar.
b) Includes Sabouraud's dextrose agar; Emmons' modification of Sabouraud's dextrose agar; BHI agar; Sabouraud's brain–heart infusion (SBHI) agar; inhibitory mold agar (IMA); mycosel or mycobiotic agars and potato flake agar.

recovery of fungi from clinical specimens, although 'room' temperature (25–30°C) is adequate. Care should be taken to provide a humid environment, primarily to prevent plated media from drying during the incubation period of 4–6 weeks. Adequate moisture can usually be achieved by placing containers of water within the incubator or placing plates in a sealed oxygen-permeable plastic bag. Other specific incubator environments are necessary for special procedures; e.g. conversion of dimorphic fungi from the mold to the yeast form requires a temperature of 35–37°C and a moist environment. Higher temperatures may be needed to test for temperature-tolerance studies, which will differentiate some fungi. It should be noted that growth at 37°C is not a requirement for pathogenic fungi that may infect anatomic sites having a lower temperature.

Blood cultures

Fungemia has become a more common event, particularly in immunosuppressed patients and those who receive broad-spectrum antibiotics, or in those with intravascular devices in place. It is common for nosocomial fungal infections to develop in these groups of patients. Further, fungemia caused by dimorphic fungi has increased over the past few years. Laboratories must be sufficiently proficient to offer a reliable blood culture system that will recover the etiologic agent in the shortest possible time.

A number of variables must be carefully considered in the provision of optimal recovery of fungi from blood. Blood should be collected at intervals as described for the detection of bacteremia (Geha and Roberts 1994). The volume of blood cultured is critical in ensuring optimal recovery with, in general, the larger the volume collected, the greater the chance for recovery. It is necessary to obtain at least 10 ml of blood in a 1:10 ratio of blood to broth in bottles, or 10 ml inoculated on to the surface of several different media after lysis-centrifugation. Automated systems may allow for use of a larger amount of blood for inoculation.

Blood culture bottles must be vented, either transiently or permanently, and the temperature of incubation should range from 25 to 30°C, with the higher temperature being preferable. The duration of incubation for most isolates of yeasts is one week, although the range of time for recovery of dimorphic fungi may extend to 4–6 weeks. Using lysis-centrifugation (with an Isolator), 3 weeks of incubation seems to be adequate. The average recovery time for yeasts and molds using the lysis-centrifugation method is 3.8 and 10.5 days, respectively (Telenti and Roberts 1989).

Media used for the recovery of fungi from blood vary with the system used in the laboratory. For the most part, media such as those used in commercially available bottles will recover yeast species adequately. The lysis-centrifugation method allows the user to select the solid media used. Yeasts are often recovered by employing sheep blood or chocolate agars. The addition of BHI, IMA and Sabouraud's dextrose agars allows for the recovery of all fungal pathogens within 2 weeks of incubation.

As a rule, broth cultures require about twice as long for recovery as the lysis-centrifugation method. *Cryptococcus neoformans* may not be recovered or the time for its recovery is significantly delayed by commercially available systems. Furthermore, the dimorphic fungi are frequently not recovered using broth media or commercial systems. However, a Myco/F/Lytic culture medium is reported potentially to offer an alternative method for the recovery of dimorphic fungi from blood (Waite and Woods 1998; Vetter et al. 2001). Other studies have not shown the Myco/F/Lytic culture medium to be superior to previously reported methods (Fuller et al. 2001).

The detection of fungemia has improved remarkably over the years and recovery time is clinically relevant. The lysis-centrifugation system is optimal when considering the recovery of all agents of fungemia; when only yeasts are considered, however, broth media or commercially available systems are probably satisfactory. The lysis-centrifugation method is preferred for the recovery of *Histoplasma capsulatum* and *Cryptococcus neoformans*; the system also has the added benefit of providing quantitative cultures.

DIRECT MICROSCOPIC EXAMINATION

A definitive diagnosis of most fungal diseases requires recovery and identification of the fungus from cultures. This often requires a period of several days to weeks for the organisms to produce enough growth and sporulation for identification. A tentative or preliminary diagnosis can often be made by microscopically detecting fungal elements present in the clinical specimen. A well-trained person, with knowledge of fungal morphology, can often provide a definitive diagnosis by this method or at least provide a tentative diagnosis days or weeks before culture confirmation.

The direct microscopic examination of clinical specimens may be as simple as placing a drop of liquid specimen on to a clean microscope slide and examining it with a light microscope, or it may involve more complex procedures, including staining of tissue. The sensitivity of direct examination depends on several factors, including quality of specimen, specimen type, quality of the microscope and, not least, the expertise of the microscopist in recognizing fungal elements and their diagnostic morphology.

If the specimen is transparent, it may be examined without treatment. If it is opaque, it must be cleared to reveal fungal elements, or the elements must be differentially stained within the specimen.

Treatment with potassium hydroxide (KOH) will clear the specimen of cells or debris Calcofluor white (Hageage and Harrington 1984); Gram's, Giemsa, Wright, periodic acid–Schiff (PAS), methenamine silver, and Papanicolaou's stains (Chandler et al. 1989; Conner et al. 1997) are satisfactory for use in detecting fungi in clinical specimens. These procedures may be performed in different areas of a laboratory, e.g. cytology, surgical pathology, hematology or microbiology; but it must be remembered that the above factors affecting sensitivity and specificity apply to any laboratory. The morphology of fungi appears essentially to be the same in other clinical specimens as it does in tissue, so it is possible to become very proficient in reading and interpreting results from a variety of specimens. Methods commonly used for detecting fungal elements in clinical specimens are presented in Table 3.

Fungi demonstrate enormous diversity in morphological features. Environmental factors play a significant role in determining how a fungus grows, so morphological diversity of fungi therefore should be expected in diseased tissue. Despite this, there is reasonable stability in the general morphology of the groups of fungi found in clinical specimens. Yeast forms are readily identifiable, but hyphae may be pleomorphic, depending on the source and host response. The microscopist must view a sufficient number of fields to ensure observation of the true morphological form of a fungus. Direct microscopic examination of clinical specimens can be very helpful in providing an early diagnosis for the clinician. The characteristics of the fungal elements commonly found in tissue and other clinical specimens are given in Table 4.

Examples of yeasts, pseudohyphae, septate and non-septate hyphae in tissue are shown in Figures 1, 2, 3 and 4.

METHODS OF IDENTIFICATION

When a fungus is recovered from a clinical specimen, a decision must be made as to its importance as a cause of disease. It is very helpful to know if the isolate is a 'classic pathogen' or one of the opportunistic fungi asso-

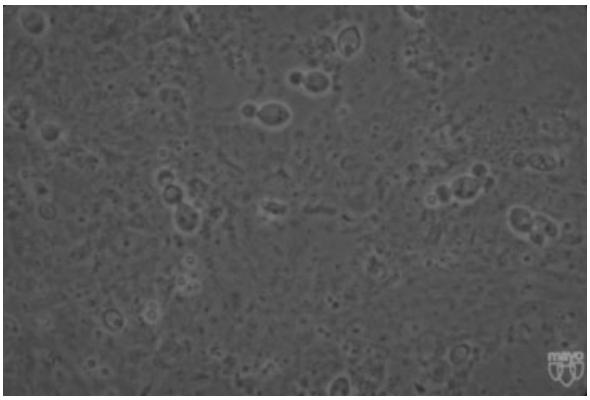

Figure 1 *Wet preparation of* Histoplasma capsulatum *var.* capsulatum *yeasts in bronchial lavage.*

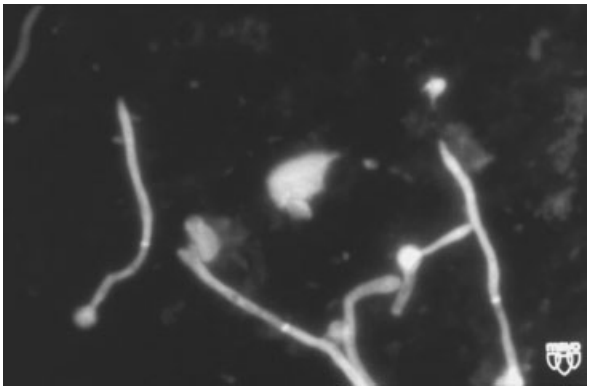

Figure 2 *Wet preparation of pseudohyphae of* Candida albicans *in scraping of oral lesion.*

Table 3 *Selected methods useful for direct microscopic detection of fungal elements in clinical specimens*

Method	Use	Time required	Advantages	Disadvantages
Calcofluor white	Detecting fungi	1 min	Can be mixed with KOH; fungi brightly fluoresce	Requires fluorescence microscope and special filters. Background sometimes fluoresces but fungi exhibit more intense fluorescence
Giemsa stain	Examining bone marrow and peripheral blood smears	15 min	Detects intracellular *H. capsulatum*	Detection is usually limited to *H. capsulatum*
Gram's stain	Detecting bacteria	3 min	Commonly performed on most clinical specimens submitted for bacteriology and detects most fungi present	Some fungi stain well; however, others (e.g. *Cryptococcus* spp.) stain weakly in some instances and exhibit only stippling. Common GS artifacts appear as yeast cells
India ink	Detecting *C. neoformans* in CSF and other body fluids	1 min	When positive in CSF, diagnostic of cryptococcosis	Negative in many cases of meningitis (non-AIDS)
Potassium hydroxide (KOH)	Clearing of specimens to make fungi more readily visible	Variable, depending on specimen	Rapid detection of fungal elements	Experience required; background artifacts are often confusing
Methylene blue	Detecting fungi in skin scrapings	2 min	Usually added to KOH; provides contrast for detection of fungal elements	Background staining of cells makes reading difficult
Methenamine silver stain	Detecting fungi in histological sections	1 hour	Best stain for detecting fungal elements	Requires specialized staining method not usually available in microbiology laboratories
Papanicolaou stain	Examining secretions for presence of malignant cells	30 min	Cytotechnologist can detect fungal elements	Requires specialized staining and a reader familiar with this stain
PAS stain	Detecting fungi	20 min; 5 min additional if counterstain is employed	Stains fungal elements well; hyphae and yeasts can be readily distinguished	*B. dermatitidis* appears pleomorphic. PAS-positive artifacts can appear as yeast cells
Wright stain	Examining bone marrow and peripheral blood smears	7 min	Detects intracellular *H. capsulatum*	Detection is usually limited to *H. capsulatum*

PAS, periodic acid–Schiff.

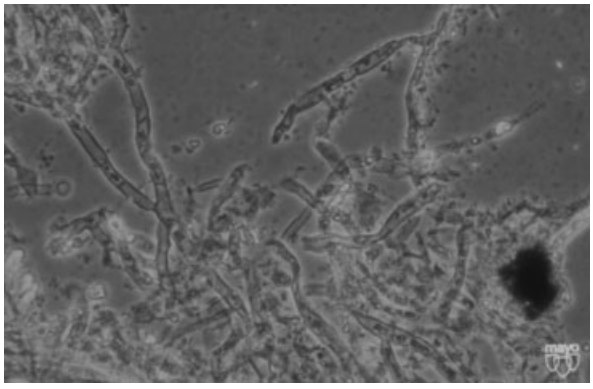

Figure 4 *Wet preparation of septate hyaline hyphae in bronchial washings.*

Table 4 *Characteristics of fungal elements seen in direct examination of clinical specimens*

Morphology of fungal elements	Organism(s)	Diameter range (μm)	Characteristic features
Yeast form	*Blastomyces dermatitidis*	8–15	Cells usually large and spherical, doubly refractile; buds usually single and attached by broad base, small forms of 2–5 μm may be seen
	Cryptococcus neoformans	2–15	Cells vary in size; usually spherical but may be football shaped; buds usually single and 'pinched off'; capsule may or may not be evident; rarely, pseudohyphae forms with or without a capsule may be seen
	Histoplasma capsulatum var. *capsulatum*	2–5	Small; oval to round budding cells; often found clustered within histocytes; difficult to detect when present in small numbers
	Paracoccidioides brasiliensis	5–60	Cells usually large and surrounded by smaller buds around periphery ('mariner's wheel appearance'); smaller cells (2–5 μm) that resemble *H. capsulatum* may be present; buds have 'pinched-off' appearance
	Sporothrix schenckii	2–6	Small; oval to round to cigar shaped; single or multiple buds present; often not seen in clinical specimens
Yeast form and pseudohyphae or true hyphae	*Candida* spp.	3–4 (yeast forms); 5–10 (pseudohyphae)	Cells usually exhibit single budding; pseudohyphae, when present, are constricted at ends and remain attached like links of sausage; true hyphae, when present, have parallel walls and are septate
Yeast form and hyphae in ski Yeast form in tissues	*Malassezia furfur*	3–8 (yeast forms); 2.5–4 (hyphae) 2.5–4.0 (yeast)	Short, curved hyphal elements usually present along with round yeast cells that retain their spherical shapes in compacted clusters; when found in skin exhibit monopolar budding, small broad base at point of attachment of buds
Spherules	*Coccidioides immitis*	10–200	Spherules vary in size; some contain endospores, others are empty. Adjacent spherules may resemble *B. dermatitidis*; endospores may resemble *H. capsulatum* but show no evidence of budding. Spherules may produce multiple germ tubes if direct preparation is kept in moist chamber for ⩾24 hours; hyphae may be found in cavitary lesions
Sporangia	*Rhinosporidium seeberi*	6–300	Large, thick-walled sporangia containing sporangiospores; mature sporangia are larger than spherules of *C. immitis*
Wide, non-septate hyphae	Zygomycetes: *Mucor* spp; *Rhizopus* spp. and other genera	10–30	Hyphae are large, ribbon-like, often fractured or twisted. Occasionally, septae may be present, branching usually at right angles. Smaller hyphae overlap those of *Aspergillus* spp., particularly *A. flavus*
Hyaline septate hyphae	Dermatophytes: skin, hair and nails	3–15	Hyaline septate hyphae commonly seen; chains of arthroconidia may be present
	Aspergillus spp.	3–12	Hyphae are septate and exhibit dichotomous, 45° angle branching; cannot be distinguished from other hyaline molds; larger hyphae may resemble those of zygomycetes
	Geotrichum spp.	4–12	Hyphae and rectangular arthroconidia are present and are sometimes rounded. Irregular forms may be present
	Trichosporon spp.	2–4 by 8	Hyphae and rectangular arthroconidia are present and are sometimes rounded. Blastoconidia may be produced, but are difficult to observe
	Scedosporium aprospermum (cases other than mycetoma)	3–12	Hyphae are septate and are impossible to distinguish from those of other hyaline molds, e.g. *Aspergillus* spp.
	Fusarium spp.	3–12	Hyphae are septate and are impossible to distinguish from those of other hyaline molds, e.g. *Aspergillus* spp.

(*Continued over*)

Table 4 *Characteristics of fungal elements seen in direct examination of clinical specimens (Continued)*

Morphology of fungal elements	Organism(s)	Diameter range (μm)	Characteristic features
Pheoid septate hyphae	*Bipolaris* spp. *Curvularia* spp., *Exserohilum* spp., *Exophiala* spp., *Phialophora* spp., *Wangiella dermatitidis*, *Cladophialophora bantiana*	2–6	Pheoid polymorphous hyphae are seen; budding cells with single septa and chains of swollen rounded, sometimes budding, cells may be present. Occasionally, aggregates may be present when infection is caused by *Phialophora* and *Exophiala* spp.
	Phaeoannellomyces elegans	1.5–5	Usually, large numbers of frequently branched hyphae are present along with budding cells
Muriform cells	*Cladophialophora carrionii*, *Fonsecaea compacta*, *Fonsecaea pedrosoi*, *Phialophora verrucosa*, *Rhinocladiella aquaspersa*	5–20	Pheoid, round to pleomorphic, thick-walled cells with transverse septa. Commonly, cells contain two fission plates that form a tetrad of cells. Occasionally, branched septate hyphae may be found in addition to muriform cells
Granules	*Acremonium falciforme*, *A. kiliense*, *A. recifei*	200–300	White, soft granules without cement-like matrix
	Curvularia geniculata, *C. lunata*	500–1 000	Black, hard grains with cement-like matrix at periphery
	Aspergillus nidulans	65–160	White, soft granules without cement-like matrix
	Exophiala jeanselmei	200–300	Black, soft granules, vacuolated, without cement-like matrix, made of dark hyphae and swollen cells
	Fusarium spp.	200–500	White, soft granules without cement-like matrix
	F. moniliforme, *F. solani*	300–600	
	Leptosphaeria spp.	400–600	Black, hard granules; cement-like matrix; periphery composed of polygonal swollen cells and center composed of hyphal network
	L. senegalensis, *L. tompkinsii*	500–1 000	
	Madurella grisea	350–500	Black, soft granules without cement-like matrix; periphery composed of polygonal swollen cells and center composed of hyphal network
	M. mycetomatis	200–900	Black to brown hard granules of two types: (1) rust brown, compact, and filled with cement-like matrix; (2) deep brown, filled with numerous vesicles, 6–14 μm in diameter, cement-like matrix in periphery and central area of light-colored hyphae
	Neotestudina rosatti	300–600	White, soft granules with cement-like matrix at periphery
	Scedosporium aprospermum	200–300	White, soft granules composed of hyphae and swollen cells at periphery in cement-like matrix
	Pyrenochaeta romeroi	300–600	Black, soft granules composed of polygonal swollen cells at periphery; center is network of hyphae; no cement-like matrix

ciated with infection of immunocompromised hosts. A rapid identification of the fungus is thus very important for diagnosis and early management of fungal diseases (Kwon-Chung and Bennett 1992).

Morphology

The standard method for identifying moulds is by observing their colonial and microscopic morphological features and following taxonomic keys to make an identification. This usually entails observing, on standardized media, the rate of growth, colonial morphology and color of the colony, and microscopic morphology including: formation of conidia; conidial arrangement; conidial morphology and pigmentation; and hyphal morphology and pigmentation. There is considerable variation in the characteristics of molds and their identification is difficult for an untrained laboratory worker.

Yeasts can be identified by morphological and biochemical methods. Details on the identification of yeasts can be found in Candidiasis and Cryptococcosis. There are many commercial systems available for identifying yeasts on the basis of biochemical reactions. Most of these systems are very good for the identification of the clinically important yeasts, provided that their morphology is considered when interpreting the biochemical results. Most systems,

Table 5 *Commonly used media for determining morphology of fungi*

Organism	Media
Aspergillus spp.	Czapek's Dox agar
Pigmented molds	Cornmeal agar, Sabouraud's dextrose agar, Lactrimel agar
Dermatophytes	Cornmeal agar, potato dextrose agar
Hyaline molds	Cornmeal agar, Sabouraud's dextrose agar (Emmons' modification), potato flake agar, inhibitory mold agar
Yeasts	Cornmeal agar
Zygomycetes	Cornmeal agar, potato flake agar, Water agar, Sabouraud's dextrose agar

however, have serious flaws in identifying some yeasts without morphological information. It is necessary to use standardized media to be able to observe consistent morphological features that are stable enough to be used in taxonomic keys. Some of the more commonly used media are listed in Table 5.

Incubation requirements for morphological media are generally the same as for primary isolation. When a fungus appears mature enough to have formed conidia, it is necessary to examine the microscopic structures. Looking at colonies under a stereoscopic microscope is sometimes helpful for observing large fruiting structures and conidial arrangements. Culture dishes should not be opened during observation.

More detailed observation requires removal of a small representative sample of a portion of the colony, and its transfer to a drop of lactophenol cotton blue or aniline blue placed on a clean microscope slide.

The colony segment is carefully torn apart, using inoculation wires or picks; a clean coverslip is then added and the specimen is observed under the low- and high-power objectives of a microscope. If the fungal colony is soft, a portion is placed in the dye on a microscope slide and the specimen is covered with a glass coverslip, which is pressed down with a pencil eraser to flatten the specimen. An alternative and often-superior method for observing the morphology of molds is the 'Scotch tape' technique. A strip of clear Scotch tape is pressed firmly on the colony; it is then placed in a drop of lactophenol cotton blue or aniline blue dye on a clean microscope slide. The tape holds hyphae and reproductive structures in place and serves as a coverslip.

Most morphological structures can be observed adequately by transmitted light microscopy, but some unusual structures, e.g. annellides, may require more sophisticated microscopy, such as phase contrast or a high-resolution digital photograph that can be enlarged. A detailed description of the morphological characteristics of fungi is given in Fungal structure and morphology.

Identification of dimorphic fungi using nucleic acid probes

The definitive identification of the dimorphic fungi *Histoplasma capsulatum*, *Blastomyces dermatitidis* and *Coccidioides immitis* has traditionally been made on the basis of the microscopic morphology of both mold and parasitic (yeast or spherule) forms. In vitro conversion of the mould form to its corresponding yeast form for *H. capsulatum* and *B. dermatiditis* is often difficult and requires an extended period of time. Conversion of *C. immitis* requires specialized media and conditions; clinical laboratories do not undertake it. Laboratories with little experience have found that it is impractical to use the in vitro conversion process.

The exoantigen test (Kaufman and Standard 1978) was considered for many years as the method of choice for the definitive identification of dimorphic fungi. The method relied on the principle that soluble antigens are produced by fungi when grown in a broth medium and that they can be extracted and concentrated and subsequently reacted with serum known to contain antibodies specific for a particular species. This immunodiagnostic method utilized the immunodiffusion test as a means of detecting the species-specific antigens produced by these dimorphic fungi.

The exoantigen test has been replaced by specific nucleic acid probes that provide a more rapid and specific identification. The identification of dimorphic fungi using nucleic acid probes has changed the laboratory aspects of clinical mycology more than any other single contribution made during the past few years. This technology allows for the rapid (one hour) identification of the organisms, whether found in mixed culture or not. The probes are commercially available from Gen-Probe Incorporated (San Diego, CA) and are genus and species specific.

Fungal cells are lysed and the ribosomal RNA is hybridized to a DNA probe which has been labeled with an acridinium ester (Stockman et al. 1993). In short, the hybrids are detected by the chemiluminescence of the attached probe. Chemiluminescence is quantitated using a luminometer and the limits for positivity are well defined. The method is simple and rapid. It is recommended for laboratories that deal with dimorphic fungi with some frequency. Financial considerations must be made before incorporating these probes into a clinical laboratory's diagnostic routine; however, the time saved for patients awaiting a diagnosis is dramatically shortened and appropriate therapy can be instituted promptly.

FUNGAL SEROLOGICAL TESTING

Serological procedures, together with clinical and patient history data, are often useful in obtaining an early diagnosis of the life-threatening systemic fungal diseases (Kaufman et al. 1997). Most of the currently available, standardized, serological procedures detect antibodies to specified fungi; they are, therefore, of limited value in diagnosing disease in immunocompromised patients. This deficiency is being addressed by the rapid development of tests for fungal antigens.

The use of serological tests to measure antibodies is most useful in the diagnosis of acute, systemic, fungal diseases. Agglutination, precipitation (immunodiffusion), complement fixation, and enzyme immunosorbent assays are widely available commercially for use in the diagnosis of aspergillosis, blastomycosis, coccidioidomycosis, histoplasmosis and paracoccidioidomycosis. The most widely used is the assay for the detection of *Histoplasma* antigen (Durkin et al. 1997). This test has proven useful for the detection of antigenemia in patients having disseminated disease (Wheat et al. 1986), particularly those with acquired immunodeficiency syndrome (AIDS) (Wheat et al. 1992). Serological tests have been developed commercially for detecting cryptococcal and candida antigens. The latex agglutination test for cryptococcal capsular antigen is one of the most reliable fungal serological tests for use in diagnosing cryptococcal meningitis. The role of tests for antigens of *Candida* spp. in diagnosing candidemia is unclear. Considerable effort is being directed towards developing tests to detect fungal antigens, in the serum and other body fluids, as a means of diagnosing the increasing number of opportunistic fungal diseases in immunocompromised patients (Yeo and Wong 2002). The galactomannan EIA assay offers promise of being an important test for invasive aspergillosis (Wheat 2003). A listing of the currently commercially available serological tests and their uses can be found in Table 6. A more detailed description of fungal immunoserology can be found in Mycoserology and molecular diagnosis.

LABORATORY SAFETY

Biosafety in the clinical laboratory is of the utmost importance to the laboratory worker and to those who work in adjacent areas. The fungi produce conidia that are easily aerosolized and may contaminate the laboratory, air-handling systems, and, in some instances, other cultures and specimens. Comprehensive safety guidelines should be available to laboratory workers to minimize the risk of acquiring infection in this setting. The following are guiding principles which should be remembered and practised by laboratory personnel:

- All clinical specimens should be considered as infectious and universal precautions must be used to protect laboratory personnel.
- All fungi should be considered as potentially pathogenic. Some laboratory personnel may be immunocompromised and highly susceptible to infection.
- Even fungi that are not endemic to a certain locale must be taken into consideration when making a diagnosis. Cultures of *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Paracoccidioides brasiliensis* and *Penicillium marneffei* may be encountered in any laboratory as a result of the ease of travel today.
- All molds must be handled within a biological safety cabinet to prevent aerosolization of their conidia within the laboratory.
- When laboratory-teaching rounds are done, cultures of molds should not be passed around from person to person; they should remain on the bench to prevent inadvertent breakage of a culture dish or tube.
- When flaming loops or wires, excess inoculum should be removed before flaming. Flaming should be used to decontaminate the entire wire or loop, not only the tip.
- Culture dishes can be used safely in the laboratory; however, lids should be removed only inside a biological safety cabinet. Lids should be taped entirely or in two places to prevent inadvertent opening.
- Biological safety cabinets must be certified annually to ensure proper protection to the laboratory worker.
- Work surfaces must be wiped with a disinfectant after a spill and before leaving for the day. A number of suitable disinfectants are available; however, hypochlorite is cost-effective and is suitable.
- A laboratory safety manual must be prepared that includes procedures for treatment of laboratory spills, an evacuation plan, and overall laboratory decontamination in the event of biohazardous spills.

MOLECULAR TESTING

When one reviews the literature relating to molecular methods used in fungal diagnosis, a plethora of reports are found. The number of reports is so numerous that it is difficult to determine which are of practical value in the clinical laboratory (Sandhu et al. 1995; Chen et al. 2002; Erjavec and Verweij 2002; Stevens 2002; Yeo and Wong 2002). Many of the studies have been validated only by the reporting investigator; many used only a small number of samples for the validation, and most lacked strong clinical correlation. However, these studies represent the beginning of a molecular era that will evolve over the next several years and these tests will find their particular niches within the laboratory. Most clinical mycology laboratories will not replace all traditional testing with molecular methods due to the extremely large number of fungi that are capable of causing human disease. To develop testing that will detect each etiologic agent would be neither practical nor cost-

Table 6 *Commonly used fungal serological tests*

Disease	Test antigen(s)	Interpretation
Aspergillosis	CF (aspergillin)	Titer ⩾1:32 suggestive of infection
	Aspergillus fumigatus, *A. niger* and *A. flavus*	Higher titers have a stronger correlation with disease
	ID, aspergillin EIA, galactomannan assay uses a monoclonal antibody	Multiple precipitin bands increase the suspicion of active disease. Positive in 95% of cases with fungus ball; 50% with bronchopulmonary disease. May be positive in invasive disease, rarely. Galactomannan antigen is detected in some patients, more evaluations are needed to determine efficacy. Piperacillin-tazo bactam cause false positive reactions
Blastomycosis	CF, yeast form of *Blastomyces dermatitidis*	Titers of ⩾1:8 are significant. Higher titers may be more indicative of disease. Cross-reactions occur in patients with histoplasmosis and coccidioidomycosis may occur. High percentage of cases are negative
	ID, yeast culture filtrate	Specific band for A antigen. Many culture-proved cases are negative
Candidiasis	ID, *Candida albicans* sonicate	Most cases have bands; however, high percentage of normal populations have antibody to *C. albicans*
	LA, yeast cytosol or mannan	⩾1:4 or 1:8 are considered positive; difficult to interpret; must have clinical correlation
Coccidioidomycosis	CF, coccidioidin	Titer ⩾1:2 significant. Higher titer parallels severity of disease. May cross-react with patients with histoplasmosis and blastomycosis. May not be positive early in disease
	ID, coccidioidin	Specific F antigen; correlates with CF results
	TP, coccidioidin	Detects IgM during first 3 weeks of disease
	LA, coccidioidin	Correlates well with CF
	EIA, coccidioidin	A positive relative EIA value indicates disease. Separate test for IgG and IgM. Positive IgM indicates early disease
Cryptococcosis	LA, anticryptococcal capsular polysaccharide	Detects cryptococcal capsular polysaccharide in cerebrospinal fluid or serum. Any titer significant. Rheumatoid factor causes false positive; 95% of *Cryptococcus* meningitis cases are positive *neoformans*
	EIA, antibody to cryptococcal capsular polysaccharide	Appears to be more sensitive than LA test. Use as quantitative test not confirmed
Histoplasmosis	CF, histoplasmin (mycelial form)	⩾1:8 significant. Higher titers parallel more severe disease. May be influenced by skin test
	CF, yeast cells (yeast form)	⩾1:8 significant. Higher titers parallel more severe disease. Usually higher titer than mycelial form. May cross-react with blastomycosis and coccidioidomycosis
	ID Histoplasmin	Specific bands to H and M antigens. 'M' band usually appears first in disease and persists. 'H' band is associated with active disease and often disappears during therapy. 1.0–2.0 indicates a weak positive; suggest repeat; 2.1–4.0, positive; 4.1–10.0, moderate positive; >10.0, highly positive (all values are EIA units).
	Histoplasma Immunosorbent Assay[a]	–
Sporotrichosis	LA, Yeasts of *Sporothrix schenckii*	Titer ⩾1:80 usually indicates active disease. Usually negative with systemic sporotrichosis

CF, complement fixation; EIA, enzyme immunoassay; ID, immunodiffusion; LA, latex agglutination; TP, tube precipitin.
a) Testing performed only by MiraVista Laboratories, Indianiapolis, IN.

effective; but, testing for selected fungi is certainly possible and work is already well underway to provide this to the clinical laboratory. However, amplification with universal fungal primers followed by sequencing of the amplicon offers the promise of being able to detect a variety of fungi in clinical specimens.

Molecular assays will allow the laboratory to detect and/or identify the fungi present in clinical specimens whether it is done by nucleic acid amplification technology or by specific probes or nucleic acid sequencing. This is an exciting time since molecular technology is in its infancy in routine clinical laboratories and many new developments lie ahead. A brief summary of what has been done to date will be presented; however, it will not be exhaustive. In this way, the reader will have a general appreciation for what has been currently accomplished

and, perhaps, what might find its way into the routine clinical laboratory. Before choosing a specific molecular testing method, a thorough comparison of useful methods should be completed so that the best can be verified and validated prior to being used. Further, standards must be set for test performance analytical and clinical sensitivity; specificity, and reproducibility within the laboratory. We must develop a focused and standard approach that is optimal for patient diagnosis. Hopefully this will occur, but it may not be realistic with the financial and personnel constraints imposed on clinical laboratories currently. Molecular testing should be embraced with great enthusiasm and excitement since it has the potential to provide for a more accurate and sensitive diagnosis of fungal infections in patients whom we serve.

Direct detection of the nucleic acid of fungi in clinical specimens

Immunocompromised patients and fungal infections are being seen at a much higher rate than ever before. Traditional cultures often require an extended time before the etiologic agent can be recovered and identified. During this, the disease may have progressed to a point where therapy may be ineffective; molecular detection should allow for monitoring patients on a periodic basis for the presence of circulating nucleic acid of the infecting organism. Further, if nucleic acid can be detected in blood or urine, this would dramatically reduce the need for invasive procedures such as biopsy or bronchoalveolar lavage. Being able to start therapy at a much earlier time during the clinical course should significantly affect the survival rate of the patient with a life-threatening fungal infection.

One of the simplest approaches used has been in situ hybridization using specific nucleic acid probes for the identification of organisms in patient specimens. This method lacks amplification and is less sensitive than other assays but is useful for identifying fungi that can be seen in tissue and other clinical specimens. Assays for *Aspergillus*, *Candida* and many other fungi are used primarily in pathology laboratories and are helpful when a morphological identification cannot be made (Hayden et al. 2001, 2002, 2003; Procop 2002).

Amplification assays using the polymerase chain reaction (PCR) or similar methods allow for the detection of small amounts of target DNA in clinical specimens. Specific primers with or without specific probes have been used with some success. Recent reviews by Yeo and Wong (2002) and by Chen et al. (2002), summarize specific targets used and detection methods. Assays have been developed to detect DNA of *Candida* (Chryssanthou et al. 1999; Loeffler et al. 2000a; Wahyiningshi et al. 2000; Ahmad et al. 2002), *Aspergillus* (Lass-Florl et al. 2000; Buchheidt et al. 2001, 2002; Ferns et al. 2002), *Fusarium* (Hue et al. 1999), *Cryptococcus* (Sandhu et al. 1995; Hendolin et al. 2000), *Histoplasma* (Bialek et al. 2002; Rickerts et al. 2002), *Blastomyces* (Sandhu et al. 1995; Bialek et al. 2003), *Coccidioides* (Sandhu et al. 1995), *Paracoccidioides* (Gomes et al. 2000), *Pneumocystis jirovecii* (Lindsley et al. 2001; Nevez et al. 2002), *Penicillium marneffei* (Vanittanakom et al. 2002), and dermatophytes (Turin et al. 2000).

More recent technology has utilized real time PCR using the Light Cycler offered by Roche Molecular Systems (Mannheim, Germany). Fluorescent resonance energy transfer is used to detect amplified products and the system allows for the quantification of the target DNA. Results are available within one hour of testing and sensitivity is exquisite. Loeffler has used this technology to develop assays for *Aspergillus* (Loeffler et al. 2000b), *Candida* (Loeffler et al. 2000a), and the zygomycetes (Loeffler et al. 2001). A recent report described the use of real time PCR for the identification of culture isolates of *Histoplasma capsulatum* (Martagon-Villamil et al. 2003). This study also reported the detection of *H. capsulatum* DNA in a few clinical specimens; however, these are preliminary data and clinical trials will be needed to confirm the utility of the test as a diagnostic tool. Further, the MagNApure (Roche Molecular Systems, Mannheim, Germany) automated DNA extraction system was evaluated for use with the fungi (Loeffler et al. 2002). A combination of the Light Cycler and MagNApure appears to offer great promise for the detection of fungal DNA in clinical specimens in a very rapid manner. The Light Cycler may also be used to identify organisms to the species level using specific primers and probes.

Traditionally, the identification of clinically important fungi has been made based on macroscopic and microscopic morphological features. Considering the large number of fungi in the environment that are capable of causing human disease, it is difficult to believe that molecular methods will replace conventional methods anytime soon. However, a limited number of fungi may be identified to genus and species using PCR and specific probes. Yeasts in blood cultures have been identified and most were species of *Candida* (Chang et al. 2001). *Aspergillus* (Henry et al. 2000), zygomycetes (Voigt et al. 1999), dermatophytes (Mochizuki et al. 2001; Ninet et al. 2003), and several filamentous fungi may be identified using amplification and probes. Nucleic acid sequencing has been use with great success for the identification of fungi in culture (Turenne et al. 1999). Currently, a comprehensive database of fungal sequences is available in the MicroSeq 500 microbial identification system (Applied Biosystems, Foster City, CA). This database is not yet complete, but when used with GenBank and other public databases, many fungi may be more easily be identified when compared to traditional identification methods.

The use of molecular methods is important to investigate the epidemiology and environmental sources of fungi that infect immunocompromised patients and, in some instances, immunocompetent patients. Epidemiologic typing can determine whether or not organisms share the same DNA profile and this can be related to environmental isolates to determine the point source. Most of the studies have been related to isolates of *Candida* (Stephan et al. 2002), *Cryptococcus* (Anonymous 2002), *Aspergillus* and *Fusarium* (Raad et al. 2002). The use of molecular tools has allowed for the reduction of hospital-acquired infections and their spread.

Overall, molecular methods have and will continue to have a major impact on the diagnosis and appropriate treatment of fungal infection. Analytical parameters of these methods need to be standardized to optimize sensitivity and specificity and comparative studies need to be performed to determine which are best to use in the laboratory. Ideally, tests should be as simple as possible to perform so that most clinical laboratories can use them. The most important element, clinical correlation, must be established for methods. If these criteria are met, most of the newly developed molecular-based tests will be available to all of the patients whom we serve. One needs to remember that all of us should be in the field to improve patient care and that the needs of the patient come first.

This chapter describes the application of serology and the polymerase chain reaction (PCR) to the diagnosis of systemic fungal infections. Culture-confirmation is still the cornerstone of diagnosis, and has become even more desirable as new treatment options and antifungal sensitivity testing become available. But the problem remains that positive cultures can be difficult to obtain – the yield being low, growth often slow, and biopsying a deep infected site may be difficult or impossible. Therefore, new, nonculture-based tests have been developed, usually based on detection of circulating fungal antigens or DNA, in an attempt to make diagnosis more rapid and reliable.

Traditionally the rationale behind this strategy has been that by confirming the diagnosis more quickly, antifungal treatment will be initiated earlier thereby reducing mortality (Horn et al. 1985) – confirmation being particularly important when the only treatment option was conventional amphotericin B. Now that safer antifungals are available, there is greater use of antifungal prophylaxis in high-risk groups and of empiric therapy in symptomatic patients – but these approaches are not without problems. Paralleling the increased use of fluconazole in the early 1990s, fluconazole-resistant non-*albicans* species of *Candida* have become commoner (Kontoyiannis and Lewis 2002). Amphotericin B resistance is much rarer but well documented. Greater empiric use of antifungal drugs inevitably exposes a larger number of patients, some inappropriately, to the risk of drug-induced toxicity and substantially increases pharmaceutical costs. Therefore the goal should remain to develop reliable diagnostic tests to provide an early diagnosis, preferably before beginning treatment.

Some of these assays are commercially available, whereas others are still under research and development. Inevitably the latter have not been widely assessed outside the originating research laboratory, although they may take advantage of the latest technical advances. Assessing the diagnostic value of a serology test raises questions such as those given in Table 1. For the referring clinician to get the most out of serodiagnostic assays, it is important that they provide a full clinical history, ascertain the frequency with which sera should be examined, and, where possible, avoid repeated freeze-thawing of samples.

CANDIDIASIS

Clinical diagnosis of invasive (systemic and disseminated) candidiasis is hampered by a lack of specific features in most cases. Confirmation of the diagnosis from blood cultures tends to be slow (growth taking 2–5 days) and insensitive. Blood cultures are negative in about half of necropsy-proven cases (de Repentigny and Reiss 1984). Recovery from blood cultures can be improved using lysis-centrifugation or the BACTEC high-blood-volume fungal medium (Telenti and Roberts 1989; Wilson et al. 1993), but the sensitivity of even the most advanced blood culture systems becomes progressively poorer when fewer than three deep-tissue sites are infected (Berenguer et al. 1993). In chronic, hepatosplenic candidiasis, only five out of 60 cases had positive blood cultures (Thaler et al. 1988; Kauffman et al. 1991).

A single positive blood culture or culture from a normally sterile organ, body cavity, or fluid, in a

Table 1 *Assessment of serodiagnostic tests for systemic fungal infections*

Question	Example
How frequently should sera be examined?	Mannanemia is transient so frequent sampling is essential for detecting DC
How sensitive is the assay in different forms of the infection?	Acute DC versus hepatosplenic candidiasis; ABPA versus aspergillosis
How sensitive is the assay at different stages of the infection?	ID tests for dimorphic fungi usually miss early primary infections when IgM predominates
Is serology likely to make the diagnosis before other diagnostic procedures?	Cryptococcal RPLA tests, when direct microscopy is negative
Is sensitivity affected by the underlying condition?	Neutropenia; AIDS
Can it be used to distinguish between systemic infection and colonization?	Generally true of candidal antigen detection, but not candidal antibody assays
Can it be used prognostically?	Cryptococcal RPLA tests; serial measurement of candidal antibodies
Can it be used to monitor response to treatment and to detect relapses?	Cryptococcal RPLA tests; *Aspergillus* galactomannan tests; some candidal antigen detection systems; *Histoplasma* antigen detection in AIDS
Is the antigen detected stable to heat or protease treatment or freeze-thawing?	Protease pretreatment is essential for immune complex dissociation before mannan detection
Is the assay species specific?	Assays for *C. albicans* mannan miss *C. krusei*
Can the assay determine intrinsic (species dependent) or acquired antifungal resistance?	Potentially PCR versus resistance genes; species-specific targets, e.g. *Candida* mannan
Known causes of false positives?	*T. beigelii* with cryptococcal RPLA tests
Known causes of false negatives?	Prozone effect with cryptococcal RPLA tests
Reagent costs and hands-on time	Relatively high for PCR
Trained staff, special equipment, and facilities	GLC; becoming less of a problem with PCR

ABPA, allergic bronchopulmonary aspergillosis; AIDS, acquired immune deficiency syndrome; DC, disseminated candidiasis; EIA, enzyme immunoassay; GLC, gas–liquid chromatography; ID, immunodiffusion; IgM, immunoglobulin M; PCR, polymerase chain reaction; RPLA, reverse passive latex agglutination.

septic patient, is in practice enough to start therapy, but care should be taken to avoid contamination. For example, preferably, blood cultures should be taken percutaneously rather than through an intravenous line – which may have become colonized. In the latter case, simply removing the infected line may resolve the infection, provided the *Candida* has not already spread, via the bloodstream, to set up a second focus of infection.

Serology and PCR are particularly useful in helping to support the diagnosis in suspected cases in whom culture-confirmation cannot be obtained. They can help distinguish disseminated candidiasis (DC) from transient candidemia or heavy colonization. They can also be used to screen high-risk patients or monitor response to treatment in known cases. Development of these assays is complicated by the diversity of candidiasis: a test designed to detect circulating candidal antigen in acute DC will not necessarily detect heptosplenic candidiasis or localized infections such as candidal peritonitis or endophthalmitis. Sensitivity may also vary between different patient populations (such as neutropenic compared to non-neutropenic). Another increasingly important challenge is the detection of a wide range of species, not just the commonest, *Candida albicans*, and ideally their speciation, as an indication of their probable antifungal sensitivity pattern.

Candida antibodies

Several kits for measuring antibodies to *Candida* spp. are commercially available (Gutierrez and Maroto 1993; Ruchel 1993), but these are intrinsically flawed because antibody often occurs in superficially infected individuals, antibody takes time to develop, and patients with worsening candidiasis often fail to make or sustain a detectable antibody response (Matthews et al. 1984, 1987). An important exception is endocarditis caused by *Candida* spp. Here the antibody is raised and this may be of diagnostic value (Dee and Rytel 1977). In invasive candidiasis, the development of a good antibody response has been used as a marker of recovery, whereas lack of antibody is strongly indicative of a bad prognosis. This lack of antibody may reflect antibody consumption or host immunosuppression.

Cand-Tec latex agglutination assay

The first of the commercially available antigen-based diagnostics was the Cand-Tec test developed by Gentry et al. (1983) and marketed by Ramco Laboratories Inc., Houston, TX. It is an example of reverse passive latex agglutination (RPLA), latex particles being sensitized with rabbit antibodies raised against heat-killed blastoconidia.

The target antigen has not been fully characterized but is proteinaceous, clearly distinct from mannan, and could not be found in the culture supernatant of *Candida* spp. by Ruchel (1989a). It is heat labile at 57°C.

Considerable variation in the success rate of this particular test is reported in the literature, with sensitivities ranging from 33 percent (Burnie and Williams 1985) to 71 percent (Fung et al. 1986), but more commonly around 44 to 48 percent (Kahn and Jones 1986; Lemieux et al. 1990; Herent et al. 1992). This probably reflects differences in the patient population being examined and the threshold titer regarded as significant. Burnie (1991a) found that the test gave a better bimodal distribution between colonized and systemically infected patients when assessed using postoperative patients with DC rather than neutropenic patients. This could possibly be related to the higher frequency with which neutropenic patients produce the immunoglobulin IgM over IgG, which may lead to less free antigen being present (Matthews et al. 1987) or to a need for the antigen being measured to be processed by leukocytes (Ruchel 1993). In the instructions that come with the kit, a titer of 1:4 is regarded as positive. Both Burnie and Williams (1985) and Ruchel (1989b) commonly observed weakly positive titers (1:4) in neutropenic patients with DC. Although a low threshold is necessary in neutropenic patients, in order to retain sensitivity, a higher cutoff point of 1:8 is probably more accurate in non-neutropenic patients to raise specificity.

Candidiasis caused by species such as *Candida krusei*, *Candida lusitaniae*, and *Candida parapsilosis* is not readily detected by Cand-Tec (Ness et al. 1989; Ruchel 1993). Fungal infections caused by *Aspergillus* spp. (Ness et al. 1989; Phillips et al. 1990; Ruchel 1993) or *Cryptococcus neoformans* (Lemieux et al. 1990) can give a positive Cand-Tec result. False positives occur as a result of rheumatoid factor and this needs to be excluded. Burnie and Williams (1985) found 12 percent of rheumatoid factor-positive sera gave false-positive reaction with titers as high as 1:8. The importance of frequent, preferably daily, serum sampling to raise sensitivity was also emphasized. The test proved helpful in monitoring response to therapy, titers falling as the patient recovered and rising during relapse.

In conclusion, Cand-Tec does have a limited, but sometimes useful, role to play in the diagnosis and management of DC, particularly if care is taken to exclude rheumatoid factor-positive patients, daily sera are available, and titers are interpreted in the context of whether or not the patient is neutropenic. Its greatest asset is that it is quick and easy to perform.

Mannan

The first of the circulating antigens for *Candida* spp. to be fully characterized was the cell wall mannoprotein or mannan, consisting of the carbohydrate homopolymer mannose plus small amounts of protein and phosphate. This antigen is stable and resistant to boiling, protease treatment, and acidic pH. In the serum, mannan is found in immune complexes and the first step in its detection is the dissociation of these complexes by protease digestion, exposure to extremes of pH (such as NaOH at 56°C for 2 hours), boiling, or heat extraction.

Some of the first assays developed for its detection were enzyme-linked immunoassays (EIA) based on indirect inhibition (Segal et al. 1979; Meckstroth et al. 1981). These were superseded by the double antibody sandwich EIAs, developed by several different groups, reviewed by Reiss and Morrison (1993). These had the advantage that absorbance units could be directly converted into concentration (ng/ml). Specificity was consistently high, probably helped by the fact that sera were first heat treated to dissociate immune complexes, but sensitivity varied from 23 percent (Lemieux et al. 1990) to 90 percent (Fujita et al. 1986). Factors that probably influenced sensitivity included the quality of the antibody probe, the infecting species of *Candida*, the patient's underlying condition, frequency of serum sampling and time of collection relative to disease severity.

The relative species specificity of mannan antibodies is well documented. Nakamura et al. (1991), using an avidin-biotin-amplified EIA with an overall sensitivity of 84 percent for DC, found the lower limits of mannan detection were 1.0–2.8 ng/ml for *C. albicans*, *Candida tropicalis*, and *C. parapsilosis*, 6.7 ng/ml for *Candida guilliermondii*, 20 ng/ml for *Candida glabrata*, and more than 50 ng/ml for *C. krusei*. By including antibodies to the mannan of *C. krusei* as well as *C. albicans*, Fujita and Hashimoto (1992) identified a case of DC caused by *C. krusei* which was only detectable with the homologous antibody. They noted a further six cases of *C. glabrata* DC in whom serum mannan could not be detected by either antibody.

Therefore, incorporation of antibodies to the mannan of several species of *Candida* improves the performance of these assays. The greatest limitation, however, is probably that the circulation of mannan is only transient (Kahn and Jones 1986; Herent et al. 1992). In the rabbit, the serum half-life of mannan was only 2 hours (Kappe and Muller 1991). As a result of the fast clearance of mannan from the blood, tests for mannan must be performed frequently. Studies in which a large number of sera have been examined per patient, or samples have been collected when DC was most severe, are likely to give higher sensitivities.

Sensitivities reported for RPLA tests for mannan have varied from 0 to 81 percent. The highest sensitivity was obtained by Bailey et al. (1985) who used their own RPLA assay with polyvalent rabbit antisera raised against heat-killed *Candida* spp. and dissociated immune complexes with protease and heat. Sensitivity was 81 percent (17 of 21 patients) for DC, 60 percent (three of

five) for candidemia and 40 percent (four of 10) for esophagitis. Five of six cases of DC caused by *C. tropicalis* were also detected. It was negative in patients with endophthalmitis or superficial candidiasis. One false positive occurred in 86 controls. Mannan was, however, reliably detected only late on in the course of infection. Sera examined during the penultimate week before death were less than 50 percent likely to be positive. Another disappointing feature was the lack of correlation between antigen titer and severity of infection.

There are two commercially available kits for the detection of mannan by RPLA: one uses a polyclonal antibody probe (the LA-Candida Antigen Detection System, Immuno-Mycologics, Inc., Norman, OK) and the other a monoclonal antibody (Pastorex *Candida*, BioRad, Marnes-la-Coquette, France). Using the former, Fung et al. (1986) failed to detect mannan in 24 patients who had positive cultures for *C. albicans*, six of whom had DC. These results were inferior to Cand-Tec which had a sensitivity of 71 percent and a specificity of 98 percent, using a titer of 1:8 or greater as the criterion for dissemination. Disappointing results were also obtained by Phillips et al. (1990). With the Pastorex test, Herent et al. (1992) detected mannan in 10 of 19 patients with DC (52.6 percent) compared with nine positives using the Cand-Tec test. Specificity was 100 percent for Pastorex and 98 percent for Cand-Tec. Ruchel (1993) detected mannan in about half the patients with DC tested with Pastorex.

The RPLA test may be intrinsically less sensitive than EIA. Fujita and Hashimoto (1992) compared RPLA and a sandwich EIA for *C. albicans* and *C. krusei* mannan in parallel with the same antibody reagents and clinical specimens. The sensitivity of the EIA was 74 percent whereas that of the RPLA was only 38 percent. A sandwich EIA is commercially available (ICON *Candida*, Hybritech Inc., Torrey Pines, CA) and has been assessed by Pfaller et al. (1993). Of 14 patients developing DC, the test was positive in 12 (86 percent) but, notably, antigenemia preceded diagnosis by culture or biopsy in just five cases. Only a single serum was available from the two patients who gave false negatives. The authors found the test easy to perform and interpret. Girmenia et al. (1997), using dot immunobinding, found that 7.1 percent of patients with transient or catheter-related candidemia had detectable mannan compared with 76.5 percent (13 of 17) patients with persistent candidemia.

In conclusion, the commercially available RPLA tests do not, on the basis of currently published reports, significantly outperform Cand-Tec, although the sensitivity of EIA may be better, and these are becoming commercially available (Erjavec and Verweij 2002). They may miss cases of DC caused by *C. glabrata* and *C. krusei*. Use of a combination of tests to detect both mannan antigen and anti-mannan antibody may improve sensitivity, since Sendib et al. (1999) found the presence of serum mannan to be inversely related to the presence of anti-mannan antibody – detecting both raised sensitivity to 80 percent, with specificity being 93 percent.

Another cell wall component, glucan, has been found circulating in patients with candidemia or invasive aspergillosis (Obayashi et al. 1995; Mori and Matsumura 1999). It is a characteristic component of fungal cell walls (except zygomycetes) but lacking in human cells, prokaryotes, and viruses. An assay for its detection is available commercially (Fungitec G-test, Seikagaku Corp., Tokyo, Japan). The test depends on the activation, by glucan, of factor G, a horseshoe-crab coagulation factor. A broad range of fungi induce reactivity, with high sensitivity (90 percent) and specificity (100 percent) being reported in patients undergoing treatment for hematological malignancies (Obayashi et al. 1995), but negative results have been observed in pulmonary cryptococcosis.

Protease

Both a circulating secreted acid protease antigen and specific antibodies have been described in patients infected with *C. albicans* (MacDonald and Odds 1980; Ruchel et al. 1988). The protease is thought to facilitate epidermal invasion. An assay detecting urinary protease in a rabbit model has been reviewed by Reiss and Morrison (1993), but there are few human data (Ruchel et al. 1988).

It is now known that there are at least seven genes encoding a family of secreted proteases in *C. albicans*, of which six are differentially expressed and one has not yet been successfully expressed (Hube et al. 1994). Different species of *Candida* secrete antigenically distinct proteases and some species, such as *C. krusei*, do not appear to secrete proteases. Na and Song (1999) found that an inhibition enzyme-linked immunosorbent assay (ELISA) for the detection of secretory aspartyl proteinase, using a specific monoclonal antibody, gave a sensitivity of 94 percent and specificity of 96 percent when applied to retrospectively selected sera from patients with invasive candidiasis.

Enolase and heat-shock protein 90

The application of immunoblotting to the serology of invasive candidiasis created the opportunity to examine the antibody responses of infected patients to a range of *Candida* antigens in one assay. This led to the identification of two immunodominant antigens which have been used as diagnostic markers: the 47 kDa antigen (Matthews et al. 1984), now identified as the carboxy fragment of heat shock protein 90 (Hsp90) (Matthews and Burnie 1989), and the 48 kDa antigen (Strockbine et al. 1984), subsequently identified as enolase (Sundstrom and Aliaga 1992; Franklyn and Warmington 1993).

Enolase is an abundant cytoplasmic enzyme involved in the glycolytic pathway of yeasts. As it is produced by all *Candida* spp., species other than *C. albicans* should also be detected by an enolase assay, although *C. glabrata* may be an exception (Walsh et al. 1991). To detect serum enolase, a liposomal sandwich-type immunoassay was developed and made available commercially (Directigen, Becton Dickinson Inc., Philadelphia, PA). Evaluating the assay prospectively in oncology patients, Walsh et al. (1991) obtained an overall sensitivity of 75 percent and specificity of 96 percent. Many patients who were positive on almost daily sampling would have been negative if sampling had occurred weekly. In a prospective comparative assessment with Pastorex, Gutierrex and Maroto (1993) found the Directigen test to be positive in eight of 10 patients (13 of 20 sera) with candidemia, with a specificity of 97.1 percent, whereas the Pastorex test remained negative. The Directigen test never became widely used and it was subsequently withdrawn by the manufacturer.

Heat-shock proteins, also known as stress proteins, are highly conserved, ubiquitous proteins which have been categorized into families, such as Hsp90, on the basis of their molecular mass and sequence homologies. They act as immunodominant antigens in a range of bacterial, parasitic, and fungal infections. Both murine monoclonal (Matthews et al. 1991a) and human recombinant antibodies (Matthews et al. 1995) to Hsp90 were protective in mouse models of the infection and an antibody to Hsp90 is currently being assessed as a therapeutic agent. The 47 kDa antigen can be isolated from the sera of systemically infected patients by affinity chromatography (Matthews et al. 1987) and was used as a diagnostic marker in a dot immunobinding assay (Matthews and Burnie 1988).

Once *C. albicans* Hsp90 had been sequenced it was possible to map the epitopes recognized by infected patients' sera. Both a conserved immunodominant epitope, LKVIRK, and a species-specific epitope recognized by about half the patients, DEPAGE, were identified (Matthews et al. 1991b). A rabbit antiserum raised against LKVIRK, again in the dot immunobinding assay, picked up 70 percent of patients with DC caused by *C. albicans*, with a further 18 percent giving weak positives and 12 percent false negatives. Two patients with DC caused by *C. glabrata* gave negative results but a patient with *C. parapsilosis* was positive. For 12 patients, multiple sera were available and here there was a good correlation with clinical outcome, titers falling in those who recovered and rising in those who died. Each of four blood culture-negative patients with severe focal infections requiring amphotericin B were positive. Colonized patients were negative or only weakly positive. All 404 uninfected control patients were negative in this series, but false positives have been observed with some other infections, possibly as a result of circulating microbial Hsp90. One possibility would be to use antibody against the conserved LKVIRK epitope to capture serum Hsp90 and a range of species-specific epitopes, such as DEPAGE in the case of *C. albicans*, for speciation.

Metabolites

Most species of *Candida*, with the exception of *C. glabrata* and *C. krusei*, produce the metabolite D-arabinitol (Bernard et al. 1981). It can be measured by gas–liquid chromatography (GLC) but, as this is a cumbersome technique, its availability as a diagnostic procedure is limited. As arabinitol is excreted by the kidney, it accumulates in patients with renal insufficiency, so an arabinitol/creatinine ratio is calculated to be independent of renal function.

An enzymatic fluorometric method has been developed as an alternative to GLC (Soyama and Ono 1985). It depends upon the oxidation of arabinitol by arabinitol dehydrogenase, with concomitant reduction of NAD, generating NADH. The initial rate of NAD reduction is proportional to the serum arabinitol content and can be measured by a recording spectrofluorometer. A potential problem is that mannitol is also reduced by arabinitol dehydrogenase producing NADH.

Several preliminary assessments have been published of the kit made commercially available by Nacalai Tesque Co. Ltd (Kyoto, Japan). Fujita and Hashimoto (1992), in a series of 58 patients with DC, reported a sensitivity of 50 percent and a specificity of 91 percent. This compared with a sensitivity of 74 percent for an EIA test for mannan. The false positives obtained (13 of 109 patients) were attributed to heavy colonization with *Candida* spp. causing a rise in serum arabinitol or interference with the fluorometric assay by mannitol. De Repentigny et al. (1985) likewise found that an EIA for mannan, combined with blood cultures, gave superior results to GLC measurement of arabinitol. In that series the low sensitivity, 13 percent, of arabinitol/creatinine ratios was associated with a significant increase in arabinitol concentrations in high-risk patients without candidiasis compared with normal blood donors. One cause of these false positives could be steroid therapy, which has been shown to raise arabinitol levels in rabbits.

Urinary samples can be used to monitor the ratio of D-arabinitol (fungal origin) to L-arabinitol (human origin) and this was found to be positive 3–31 days (mean 12 days) before blood cultures become positive or empiric therapy initiated, in immunocompromised children with systemic candidosis (Christensson et al. 1997).

PCR

The application of PCR to fungal diagnosis has been reviewed by Walsh and Chanock (1998), Buchheidt et al. (2000), and Erjavec and Verweij (2002). Early assays

were directed against a defined target gene present in a single species or genus, but now panfungal PCR primers are being used increasingly to detect a broad range of fungi, including yeasts and molds. Many of these assays are now achieving very high levels of sensitivity in-house but head-to-head comparisons and standardized, inter-laboratory assessments are as yet rare.

The first target for the development of PCR-based diagnostics for invasive candidiasis was the gene *L1A1* encoding cytochrome P450 lanosterol 14α-demethylase which catalyzes an essential step in the conversion of lanosterol to ergosterol. As ergosterol is not a component of human or bacterial cells, it is believed to be fungus specific. The enzyme is inhibited by the imidazoles. Therefore, antifungal resistance related to alteration in the sequence of this gene might potentially be used to pick up resistant yeasts. Buchman et al. (1990) carried out an assessment with 13 clinical specimens, including urine, sputa, wound fluid, and two whole bloods, all from sites that were culture positive for *C. albicans*, and in each case they were PCR positive. Among 17 additional culture-negative specimens, PCR suggested the presence of a yeast in one blood and one urine specimen. Results were available within 6 hours and it was estimated, by serial dilution of *C. albicans* mixed with fresh blood, that as few as 12 yeast cells per 0.1 ml could be detected.

Chryssanthou et al. (1994) developed a nested PCR against the same target to increase sensitivity. They also avoided the cumbersome sample preparation required for whole blood by detecting naked DNA in serum. The primers used by Buchman et al. (1990) were used for the outer pair, and an inner pair of primers was selected which gave a PCR product of the expected size. This fragment was only amplified for *C. albicans*, other faint bands appearing with *C. lusitaniae* and *C. tropicalis*. They applied it to serum and tissue samples from infected mice and the sera of patients with DC and candidemia. The nested PCR detected as little as 1 pg *C. albicans* DNA, serially diluted in water, compared with 10 pg using the outer primer pair alone. It was more sensitive than culture in mouse experiments and in seven blood culture-negative, necropsy-positive patients, five of whom gave PCR-positive sera before death (usually taken within a week of death but in one case 84 days before and therefore of doubtful significance). However, in 11 patients with proven or, in one case, suspected candidemia, 15 of 17 blood cultures were positive, compared with only 11 of 17 sera positive by PCR. These discrepancies might result partly because blood cultures and sera for PCR were not taken simultaneously.

Buchman's group followed up their earlier work on *C. albicans* by sequencing homologous genes from *C. glabrata* and *C. krusei*, and using a published sequence for *C. tropicalis* to develop a nested PCR (Burgener-Kairuz et al. 1994). The first PCR, with genus-specific primers from a conserved region, detected a wide range of yeast species when tested with purified DNA, including *C. albicans*, *C. glabrata*, *C. krusei*, *C. parapsilosis*, *C. tropicalis*, and *Cryptococcus neoformans*. The second nested PCR with species-specific primers had a detection level 10 times higher for the homologous species. Southern blots were used to confirm the nature of the PCR product and the sensitivity was increased slightly further. The sensitivity and specificity of the nested PCR on 80 culture-positive clinical specimens were 71 percent and 95 percent for *C. albicans* and 100 percent and 97 percent for *C. glabrata*, respectively. Clinical specimens often contained large quantities of leukocytes, cell debris, and bacteria, all potential sources of strong inhibitors of the PCR which could be causes of false negatives.

In a prospective study, by Morace et al. (1999), in febrile patients with hematological malignancies, the P450 lanosterol 14α-demethylase gene was amplified and the resulting amplicon digested with restriction enzymes (RE) in order to speciate the *Candida*. The polymerase chain reaction-restriction enzyme amplification (PCR-REA) was much more sensitive (92.8 percent) and faster (24–36 hours) than blood culture systems, but there was some question over the method's specificity. Posteraro et al. (2000) used the same primers to develop a PCR-reverse crossblot hybridization assay. Chryssanthou et al. (1999) undertook a prospective study in high-risk patients comparing a nested PCR against lanosterol 14α-demethylase, with urinary D/L-arabinitol ratios and three commercially available tests for the detection, respectively, of serum glucan, mannan, and the Cand-Tec assay. No single test was sufficient for diagnosis and the correlation between some of the tests was poor. This study illustrated the difficulty in evaluating these diagnostic tests because of the lack of a definitive culture-confirmed diagnosis in many cases. In a comparison of a PCR assay (targeting a rRNA gene), the β-glucan and the Cand-Tec test, Sakai et al. (2000) showed a significant correlation between the PCR and β-glucan assays and that PCR was significantly more sensitive than the β-glucan test.

Hsp90 is an alternative target, a potential source of both species-specific and conserved DNA sequences. By selecting a species-specific primer, Crampin and Matthews (1993) obtained the expected 317 bp product only with *C. albicans* and, less intensely, *C. parapsilosis*. In a prospective study on a 100 clinical specimens, 23 percent were positive by routine culture, 31 percent by extended culture, and 37 percent by PCR. The identity of the PCR product was confirmed by hybridization with an internal probe and also by obtaining the predicted restriction enzyme digest pattern. This assay was sensitive down to 50 pg of DNA (5 pg after Southern blotting) and 100 yeast cells. Generally, specimens that were culture negative or grew bacteria or germ-tube-negative yeasts gave negative PCR results. The exceptions were

four urine samples from female patients and seven high vaginal swabs from women with vaginal discharge. Five culture-positive swabs gave negative PCR results, possibly as a result of a sampling error because plates for culture were inoculated first. Whole blood seeded with *C. albicans* gave positive results only when inhibitors were removed by the glass adhesion method. Some of the other yeast species, particularly *C. glabrata* and *C. parapsilosis*, gave bands about the same size as *C. albicans*, but in each case these were accompanied by ectopic bands not seen with *C. albicans*.

Another target is the actin gene (Kan 1993). Primers were selected which amplified a 158 bp fragment and the product was confirmed by hybridization against an internal probe. This gave a lower limit of detection estimated as 10 yeast cells for clinical specimens. The assay was assessed in both experimentally infected mice and patients with candidemia. In the mouse model of candidemia, pooled plasma samples were culture and PCR positive, whereas in the thigh-abscess model they were culture and PCR negative. In the 14 blood culture-positive patients, six of whom had *C. albicans*, 11 (79 percent) gave a positive PCR. This was performed on sera rather than on whole blood. The greatest difficulty was experienced in detecting *C. krusei* and *C. parapsilosis*. Sera from 12 patients with superficial candidiasis were PCR negative as were 17 normal volunteers.

Flahaut et al. (1998) targeted the *C. albicans* secreted aspartic proteinase (*SAP*) genes, a multigene family. A single primer pair was designed to detect six of these *SAP* genes, thereby increasing the sensitivity of the test. Detection of the PCR product by EIA was found to be as sensitive as Southern blotting with a *SAP*-labeled probe, and the sensitivity and specificity, when applied to clinical samples, were 100 percent and 98 percent, respectively.

Others have deliberately selected multicopy targets such as mitochondrial or ribosomal DNA in an attempt to maximize sensitivity. Miyakawa et al. (1992), targeting a species-specific mitochondrial DNA fragment 1.8 kbp long, could detect as few as 10 yeast cells in human urine but as many as 105 cells were required in human blood before detection. They attributed this to the loss of yeast cells during precipitation from the blood and the use of too long a target. They then developed a means of coprecipitating *C. albicans* with carrier *C. tropicalis* cells, aided by a monoclonal antibody which recognized both species, and selected a shortened sequence of 120 bp. This raised the sensitivity of detection of *C. albicans* seeded into blood to 3 cells/0.1 ml (Miyakawa et al. 1993). No clinical specimens were examined.

Panfungal PCR assays directed against rDNA are increasingly being used because not only are they present in multiple copies but, as a result of slow divergence of rDNA over evolutionary time, regions of sequence conservation across entire kingdoms can be identified. Separating the multicopy rRNA gene subunits are noncoding intergenic transcriber spacers (ITS). While rRNA genes are highly conserved, the ITS regions are divergent both in sequence and size. Consequently, panfungal primers can be used to amplify the fungal DNA and then species-specific ITS DNA probes can be used to speciate the amplicon.

Using such panfungal primers, directed against a region conserved throughout the kingdom Fungi, Hopfer et al. (1993) amplified a 310 bp product from fungi, while obtaining negative results from human and bacterial DNA. This PCR detected 10–15 yeast cells, but sensitivity and specificity with clinical samples were not determined. *Hae*III digests were used to characterize the fungus into one of five groups: *Aspergillus*, *Candida*, *Cryptococcus*, and *Trichosporon*, zygomycetes, and the dimorphic fungi. Holmes et al. (1994), also targeting rDNA, co-amplified using both conserved primers, suitable for the detection of many fungal species, and *C. albicans*-specific primers, facilitating rapid speciation. A 105 bp fragment was amplified from all the yeast species tested, whereas a second 684 bp fragment was amplified only from the *C. albicans* DNA. The level of sensitivity was 15 yeast cells/ml using spiked blood specimens. Makimura et al. (1994), using primers from conserved fungal rDNA sequences, applied this to a limited number of clinical specimens, including blood and cerebrospinal fluid, and also blood samples from mice systemically infected with *C. albicans*. Their preliminary results were encouraging, suggesting PCR to be more sensitive than conventional blood cultures.

Again targeting fungal rDNA, Fujita et al. (1995) developed a microtitration plate enzyme immunoassay to detect PCR-amplified DNA from *Candida* spp. Species-specific probes for *C. albicans*, *C. krusei*, *C. parapsilosis*, and *C. tropicalis* were labeled with the digoxigenin, avoiding the use of radioisotopes. The PCR product was hybridized to both digoxigenin- and biotin-labeled probes and detected in an EIA by capture on streptavidin-coated microtiter plates. The assay detected as few as 2 cells/0.2 ml of blood seeded with *C. albicans*. Although no clinical samples were examined, this approach holds great promise. It combines the use of universal fungal primers against a multicopy target to broaden detection capabilities with identification of the fungus, using species-specific probes, in an EIA format that is particularly suitable to clinical laboratories; this has the potential for automation unlike Southern blotting. Ahmad et al. (2002) applied a seminested PCR, using panfungal primers against rDNA followed by the same species-specific primers from these four *Candida* spp., to detect and speciate from the sera of patients with candidemia: the results were in full agreement with blood culture results with respect to both positivity and species identity, and more sensitive than culture. Others have targeted ITS regions using species-specific primers in a multiplex PCR to speciate multiple fungal

pathogens in a single PCR reaction, from either fungal colonies (Fujita et al. 2001; Luo and Mitchell 2002) or positive blood culture broths (Chang et al. 2001). Luo and Mitchell (2002) found that DNA from only about half the molds (*Aspergillus fumigatus*) examined could be amplified directly from the mycelial fragments whereas DNA from every yeast colony (*Candida* spp. and *C. neoformans*) could be readily amplified. Rigby et al. (2002) have applied fluorescence in situ hybridization with peptide nucleic acid probes (DNA probe mimics) to rapid identification of *C. albicans* directly from positive blood culture bottles.

Shin et al. (1997) successfully applied PCR-EIA to identify *Candida* spp. in BacT/Alert blood culture bottles in 7 hours – 2.5 days sooner than by conventional culture. Alternatively, the variability in the length of the ITS2 region can be used to speciate fungal isolates. These size differences cannot be reliably detected by agarose gel electrophoresis and instead automated capillary electrophoresis has been used (Turenne et al. 1999; Chen et al. 2000).

Burnie et al. (1997) applied a similar semiquantitative PCR-EIA to sera from infected patients, this time digoxigenylating the amplicon during the PCR process. The assay was positive (optical density >0.1) in 28 cases of culture-confirmed DC. It was negative in 15 control patients and 13 of 16 patients with local infections. The remaining three, each of whom received amphotericin B, were positive. A universal, rather than yeast-specific, method of extracting the DNA was applied to the sera.

Einsele et al. (1997), targeting a consensus sequence from a variety of fungal pathogens present in 18S rRNA, achieved 100 percent sensitivity when two blood samples were examined in 21 bone marrow transplant patients with documented invasive fungal infections. Specificity was 98 percent. PCR remained persistently positive in patients failing to respond to antifungal therapy but cleared in those who did respond. Van Burik et al. (1998) developed a panfungal PCR assay optimized to detect *C. albicans* and *A. fumigatus* from whole-blood specimens, and obtained positive results in four patients with candidemia and three with pulmonary aspergillosis (one of these occurring a week prior to culture-confirmation by bronchoalveolar lavage). Wahyuningsih et al. (2000) successfully used the QIAamp blood kit (Qiagen, Hilden, Germany) to extract *C. albicans* DNA from human serum samples. They used fungus-specific universal primers against ITS regions corresponding to the 5.8S and 28S rRNA genes for amplification and then hybridized this to a biotinylated probe directed against a *C. albicans*-specific ITS2 region located between these two genes, on a streptavidin-coated plate. All seven patients with culture-confirmed invasive candidiasis were positive by PCR as were a further three high-risk patients.

PCR can be performed with either serum or whole blood. Bougnoux et al. (1999) formally compared serum with whole blood samples, in rabbits with candidemia, applying a nested PCR with five species-specific inner pairs of primers directed against ITS. Their results suggested that serum was the sample of choice.

Hendolin et al. (2000) applied a panfungal PCR to the detection of fungi in tissue specimens. Using broad-range fungal primers, they PCR amplified the fungal ITS region (ITS1-5.8SrRNA-ITS2) and then captured this with species-specific probes against eight fungal pathogens (*Candida* species, *Cryptococcus neoformans*, and *Aspergillus* spp.), species identification therefore relying on both specific hybridization and an assessment of PCR product length. A detection level of 0.1–1 pg of purified DNA was achieved. Of the 20 specimens, PCR was positive for 19 (95 percent), of which 10 (53 percent) were hybridization positive – compared to 12 (60 percent) positive by direct microscopy and seven (35 percent) by culture.

Reiss et al. (1998) applied TaqMan (Perkin-Elmer, Foster City, CA) PCR directed against the ITS2 region to blood cultures, to obtain species identification in 5 hours. TaqMan combines, in one step, PCR, hybridization with a fluorogenic probe, and fluorescent signal generation. Guiver et al. (2001) applied TaqMan PCR to the rapid identification of *Candida* species within 4 hours, compared to a mean of 3.5 days for conventional phenotypic tests. Alternatively, real-time species identification and quantification of fungal load in clinical specimens can be achieved with a LightCycler (Roche Diagnostics, Mannheim, Germany), which combines rapid thermocycling with glass capillaries with online fluorescence detection of the PCR amplicon (Loeffler et al. 2000).

In conclusion, PCR has the potential to offer a high level of sensitivity and specificity within hours of specimen collection. Care must be taken to avoid laboratory contamination, but automated sample preparation and use of real-time PCR is helping to standardize these procedures and reduce the risk of false positives. PCR is likely to be used increasingly, not only to confirm the diagnosis but to speciate the fungus.

ASPERGILLOSIS

The key to understanding the serodiagnosis of infection with *Aspergillus* spp. is an appreciation of the heterogeneity of the diseases that these fungi can cause and the resultant variations in host response. The three main conditions are:

1. an aspergilloma occurring in a pre-existing lung lesion
2. allergic bronchopulmonary aspergillosis (ABPA)
3. invasive aspergillosis.

In all three conditions, the prime organ involved is the lung, which means that diagnosis based on culture is dependent on obtaining adequate bronchial secretions. For aspergilloma, recovery rates vary from 31 to 91

percent (Schonheyder 1987). In ABPA, a positive sputum and the demonstration of hyphae of *Aspergillus* spp. are some of the features necessary to prove the diagnosis; detection of antibody is also essential (Wardlaw and Geddes 1992).

In invasive aspergillosis, lung involvement occurs in 90 percent of cases. The classic clinical presentation is that of unremitting fever, usually higher than 38°C, in a neutropenic patient, but 10 percent of cases occur in non-neutropenic patients in whom steroid therapy is often a complicating factor (Young et al. 1970). Dyspnea and a nonproductive cough are often absent during the early stage of the disease, but pleuritic chest pain and a pleural rub occur in 15–61 percent of patients (Young et al. 1970; Meyer et al. 1973). No sputum is produced by 50 percent of patients and two-thirds of those who do produce sputum are culture negative (Fisher et al. 1981). Positive cultures can occur in the absence of significant clinical disease and this may reflect the aspiration of conidia or possibly hyphal fragments, which transiently contaminate respiratory secretions. Tregar et al. (1985) reviewed 89 patients with positive sputum cultures. In nine cases there were two or more positives and eight of these patients were subsequently proved by histology to have invasive disease. Histological evidence of mycelial invasion from tissue biopsy is often not possible because of the clinical condition of the patient and often the presence of thrombocytopenia. Computed tomography can be used to detect lesions typical of invasive aspergillosis and has a significant input on management (Caillot et al. 1997). Blood cultures are occasionally of value in endocarditis caused by *Aspergillus* spp., but in invasive aspergillosis a positive blood culture is normally the result of contamination (Pennington 1980).

The failure of conventional techniques based on culture has led to numerous attempts to develop alternative assays. These can be grouped into antibody detection, antigen detection, and the detection of the DNA of *Aspergillus* spp. by PCR. *A. fumigatus* is the dominant species, but clinically significant numbers of infections can be caused by other species such as *Aspergillus niger* and *Aspergillus flavus*. Tests which specifically target one species may miss infection caused by a different species. Furthermore, *A. fumigatus* is a diverse microorganism phenotypically (Burnie et al. 1989); therefore strain-specific antigens must be avoided in developing antigen-based diagnostics. *Aspergillus* spp. can colonize patients without causing disease, so very sensitive tests may need to be quantified.

Allergic bronchopulmonary aspergillosis

Clinical diagnosis is dependent on the typical chest x-ray changes of fleeting alveolar infiltrates caused by eosinophilic pneumonia, or a combination of mucus plugging with segmental, lobar, or whole lung collapse. Detection of antibody is essential to the diagnosis of the disease. This includes IgE-mediated immediate-type hypersensitivity to *A. fumigatus* as defined by a positive immediate skin-prick test, a positive radioallergosorbent test (RAST), a high total IgE level (i.e. >2 500 ng/ml), and a raised IgG (Wardlaw and Geddes 1992). These can be demonstrated by radioimmunoassay and EIA, although the latter has been criticized for its lack of reproducibility (Richardson et al. 1982; Richardson and Warnock 1984). The antibody response has been further characterized by self-crossed radioimmunoelectrophoresis (Longbottom 1986). Antigens were subdivided into those with strong precipitin reactions and weak IgE and those that were poorly precipitating but showed strong IgE binding. Of these last antigens, three reacted with more than 50 percent of sera and were regarded as the major allergens.

Piechura et al. (1983) analyzed the cell sap and culture filtrate from three strains of *A. fumigatus*. Two-dimensional electrophoresis followed by gel filtration identified a major component of apparent molecular mass 150 kDa (CS2). On immunoelectrophoresis this produced a major precipitin arc with aspergilloma sera or sera of ABPA patients. On SDS-PAGE, following reduction, it produced three major bands at molecular masses of 41, 53, and 81 kDa. Kurup et al. (1986) prepared culture filtrate antigens from *A. fumigatus* by isoelectric focusing with a pH gradient of 4–6.5. A fraction with an isoelectric point of 6.5 had three components of apparent molecular masses 20, 40, and 80 kDa on two-dimensional electrophoresis. This fraction reacted in an EIA, showing high levels of IgG and IgE reactivity in patients with ABPA and of IgG in those with aspergilloma.

The advent of immunoblotting has helped with detailed dissection of the antibody response, but many anomalies arose regarding the apparent molecular masses of immunodominant antigens. These may reflect, in part, the different conditions under which the gels were run. With a gradient gel of 11–13 percent acrylamide, Brouwer (1988) identified antigens at molecular masses of 36, 50, and 100–120 kDa, the last being estimated by extrapolation. Baur et al. (1989), analyzing 28 patients at varying stages in the disease, found that IgE levels increased as the disease progressed. Immunodominant bands at molecular masses of 40, 51, and 80 kDa were observed, similar in size to the same antigens described by Piechura et al. (1983). Immunodominant antigens at molecular masses of 23 kDa and 17 kDa were thought to be identical to Ag3 (Longbottom 1986) and Ag40 (Wallenbeck et al. 1984). Ag40, along with Ag10, was isolated from a complex mixture of more than 50 precipitating antigens and identified as the major allergens in six patients with ABPA and in 80 percent of 25 patients with asthma caused by *Aspergillus* spp. (Wallenbeck 1991). Samuelsen et al. (1991), looking

at the IgE of patients exposed to *A. fumigatus*, found that bands at molecular masses of 20, 31, 44, 50, 53, 77, and 92 kDa reacted with more than 50 percent of sera. Others have described immunodominant antigens at 92 kDa, a 55 kDa glycoprotein (Teshima et al. 1993), and a protease at 32 kDa which was subsequently cloned and identified as a monoglycosylated alkaline protease with elastase activity (Moser et al. 1993, 1994). Leser et al. (1992) examined sera from 43 cases of ABPA and showed specific IgG and IgE against 12 different bands varying from 15 to 97 kDa. The IgG response broadly reflected the IgE with strong antibody responses to high-molecular-mass bands (between 66 and 97 kDa) as well as bands at 15, 35, and 40 kDa. Arruda et al. (1992) identified major antigens of 18 and 45 kDa. Of the 24 patients with ABPA, 11 had IgE to the 18 kDa antigen. Kobayashi and Miyoshi (1993), examining 10 aspergilloma patients and three ABPA patients, demonstrated IgG binding to antigens of greater than 30 kDa in all sera tested, and IgE binding to the 18 kDa antigen in seven of eight sera with a positive precipitin reaction by counterimmunoelectrophoresis (CIE). When immunoblotting sera from patients with cystic fibrosis and ABPA, Knutsen et al. (1994) observed heterogeneous IgE, IgG, and IgA responses to 11 major bands at 14, 18, 20, 34, 47, 50, 55, 61, 70, 81, and 93 kDa. IgE was more frequently detected against the bands at 47, 50, 61, 70, and 81 kDa.

Some of these bands are likely to be heat-shock proteins. Immunodominant antigens at 88, 84, 51, and 40 kDa were demonstrated by immunoblotting sera from 35 patients with ABPA (Burnie and Matthews 1991). The antigens at 88, 51, and 40 kDa were then shown to react with monoclonal antibodies against Hsp90 of *C. albicans* and the oomycete *Achlya ambisexualis*. Screening an *A. fumigatus* cDNA library with pooled sera from ABPA patients produced a clone which, on sequencing, was homologous with *Candida*, *Saccharomyces*, and human Hsp90 (Kumar et al. 1992). Expressed as a fusion protein, it reacted with the IgE and IgG of patients with ABPA.

Aspergilloma

A pulmonary aspergilloma can often be diagnosed on chest x-ray, or by computed tomography, by the characteristic sign of an opacity surrounded by a crescent-shaped translucent area. Levels of antibody are high and multiple lines can be detected by immunodiffusion (ID) or CIE against either mycelial or culture filtrates (Kurup and Kumar 1991). In patients with ABPA, the same levels of *A. fumigatus*-specific antibodies occur in both subclasses IgG1 and IgG2. The sera of patients with aspergilloma react to the carbohydrate and glycoprotein antigens of *A. fumigatus* with more IgG1 than IgG2 (Kurup et al. 1990).

Immunoblotting has been used to analyze the antibody response. Matthews et al. (1985) demonstrated bands ranging from 33 to 88 kDa with an immunodominant antigen at 40 kDa. Latgè et al. (1991) identified immunodominant antigens of 18, 28, 30, 38, 45–48, 94, 110, and 125 kDa with sera from 75 patients, but only a 35 kDa antigen reacted specifically with sera from the aspergilloma patients. The 18 kDa antigen was purified to homogeneity and related to a similar antigen found in the urine of patients with invasive aspergillosis (Haynes et al. 1990). It was subsequently shown to have ribonuclease activity (Latgè et al. 1993). Burnie and Matthews (1991) demonstrated immunodominant antigens at 40, 84, and 88 kDa. The 88 kDa antigen reacted with monoclonal antibodies against Hsp90 of *Candida* and *Achlya* spp., as did the extract from an aspergilloma removed from a patient. This gave a prominent band at 50–52 kDa. Kobayashi et al. (1993) confirmed the immunodominance of a band at 88 kDa but suggested that it was not Hsp90. Moutaouakil et al. (1993) biochemically characterized a 33 kDa serine protease but failed to demonstrate specific antibodies against it in aspergilloma patients.

Increasingly, recombinant proteins are being used as the basis of assays for the detection of specific, circulating antibodies to *A. fumigatus*. These are often highly specific and, in the case of aspergilloma, highly sensitive: 100 percent sensitivity was obtained by Holdom et al. (2000) using recombinant Cu, Zn superoxide dismutase, by Weig et al. (2001) using recombinant mitogillin protein, and by Chan et al. (2002) using recombinant galactomannoprotein.

Invasive aspergillosis

ANTIBODY DETECTION

Early investigations into the serodiagnosis of invasive aspergillosis concentrated on antibody detection. Coleman and Kaufman (1972) found precipitins in 82 percent of proven cases of invasive aspergillosis and in 83 percent of suspected cases. Positive precipitins in invasive disease were also observed by Meyer et al. (1973), Warnock (1977), and Kurup and Fink (1978).

Several groups working independently with different assays have found a correlation between rising antibody titers and recovery. Gold et al. (1980) developed a passive hemagglutination test based on sheep red cells treated with concanavalin A and sensitized with a partially purified antigen to *Aspergillus* spp. Sequential testing in 55 cancer patients, with sera available in the 2 weeks before diagnosis of invasive aspergillosis was made, demonstrated that 15 seroconverted. Recovery was associated with an increased antibody titer. Holmberg et al. (1980) developed an EIA with a concentrated culture filtrate precipitated by 75 percent saturated

ammonium sulfate. Examining material from 10 cases of invasive aspergillosis, they correlated a serial rise in EIA titer with recovery. Matthews et al. (1985) found, by immunoblotting serial sera, that antibody to an immunodominant 40 kDa antigen was notably absent or fell in titer in 12 fatal cases of invasive aspergillosis but persisted in two survivors. A solid-phase radioimmunoassay has also been developed for measurement of antibody (Marier et al. 1979).

There have been a number of studies describing immunodominant antigens. Antigens at 41, 54, and 71 kDa were described by de Repentigny et al. (1991) using a rabbit model. Fratamico and Buckley (1991), examining 172 sera from 38 patients with invasive aspergillosis, found 90 percent of sera detected a 58 kDa antigen on immunoblots. This antigen was abundant in mycelial extracts and comprised about 50 percent of the Coomassie blue-stained protein. It contained carbohydrate, staining with periodic acid–Schiff agent and binding to the lectin concanavalin A. Monoclonal antibodies raised against it reacted with a similar antigen in *C. albicans*, shown by localized cell surface immunofluorescence. They also recognized an *Aspergillus* antigen with a molecular mass of more than 89 kDa (Fratamico et al. 1991). Burnie (1995) immunoblotted sera from 55 cases of proven and 20 cases of suspected invasive aspergillosis and demonstrated immunodominant bands at 88, 84, 63, and 40 kDa. Possession of either IgM or IgG against the bands at 88, 84, and 40 kDa correlated with survival. The band at 88 kDa was heat inducible and reacted with monoclonal antibodies specific to the Hsp90 homologs of *A. ambisexualis* and *C. albicans* (Burnie and Matthews 1991). Reactivity was neutralized by cross-absorption with Hsp90.

Hamilton et al. (1995) identified a Cu, Zn superoxide dismutase which, by immunoblot, gave a sensitivity of 25 percent in cases of invasive aspergillosis (Holdom et al. 2000). Using recombinant mitogillin protein, in an ELISA, Weig et al. (2001) obtained a sensitivity of 62.2 percent and specificity of 95.4 percent (in normal blood donors), with a cutoff value of mean ±2 SD. Increasing the stringency by using a cutoff value of mean ±5 SD improved specificity by lowered sensitivity. Using recombinant galactomannoprotein, Chan et al. (2002), with a cutoff value of mean ±5 SD, obtained a sensitivity of 33.3 percent (five of 15 sera from 15 patients with invasive aspergillosis positive) and specificity of 100 percent.

ANTIGEN DETECTION

In cases of suspected invasive aspergillosis, antigen detection is generally preferred because the at-risk groups are likely to be immunocompromised and poor antibody producers. Antigen detection stemmed from the initial description of circulating galactomannan in the serum of a patient with invasive aspergillosis (Reiss and Lehmann 1979). The importance of this antigen has been confirmed in a rabbit model (Dupont et al. 1987) and in patients using radioimmunnoassay, EIA, and latex agglutination (LA) (Shaffer et al. 1979; Dupont et al. 1990).

In clinical studies, the radioimmunoassay had a sensitivity of 70–80 percent, a specificity of 90 percent, a positive predictive value of 82 percent, and a negative predictive value of 85 percent (Talbot et al. 1987). Antigen was detected before invasive aspergillosis was suspected in 30 percent and before laboratory confirmation in 46 percent of patients. The main limitations were the use of radioactive material and the absence of antigen in about 25 percent of cases.

Sabetta et al. (1985) devised a competitive EIA that detected an undefined carbohydrate antigen in five of six immunosuppressed, infected rabbits and 11 of 19 patients with invasive aspergillosis. In experimentally infected rabbits, de Repentigny et al. (1987) detected circulating antigen which bound to concanavalin A with an apparent molecular mass of 50–100 kDa. The size of the galactomannan antigen was then substantiated by a monoclonal antibody which reacted with the immunodominant oligogalactoside side chains of *A. fumigatus* galactomannan recognizing 80, 62, and 49 kDa components of a hyphal homogenate (Ste-Marie et al. 1990).

Rogers et al. (1990) described two inhibition EIAs using a high-titer human serum to *Aspergillus* and a rat IgM monoclonal antibody to galactomannan, respectively. The results were encouraging in that 15 of 16 patients with invasive disease had detectable antigen at some point during their illness, but only 13 percent of sera and 20 percent of urine specimens were positive with the human serum. This improved to 18 percent for sera and 44 percent for urine samples when the monoclonal antibody against galactomannan was employed.

A commercially available RPLA test, Pastorex *Aspergillus* (BioRad, Marnes-la-Coquette, France) utilized a rat monoclonal EB-A2 specific to the galactomannan of *Aspergillus*. It reliably detected galactomannan in the sera of experimentally infected guinea pigs and showed no crossreactivity in animals with invasive candidiasis or cryptococcosis (Van Cutsem et al. 1990). Sensitivities of up to 95 percent were reported in patients with proven invasive aspergillosis (Dupont et al. 1990; Haynes and Rogers 1994), though stored sera were liable to become negative (Warnock et al. 1991; Knight and Mackenzie 1992). Hopwood et al. (1995), examining patients undergoing liver and bone marrow transplants, found that four of eight patients subsequently diagnosed as having invasive aspergillosis were Pastorex positive, but only for eight of the 187 sera examined from these four patients. In a prospective study, Verweij et al. (1995b) obtained a positive Pastorex test in eight patients who were subsequently shown to have invasive aspergillosis. The

maximum titer was 1 in 8. The initial serum sample was negative in five of the cases. Storage at −20°C for longer than 6 months resulted in a loss of reactivity in six of the 13 sera tested. A further problem was the crossreactions observed, with no defined cause, reported in five patients by Hopwood et al. (1995) and also in a serum contaminated by *Penicillium chrysogenum* (Kappe and Schulze-Berge 1993).

Styner et al. (1995) demonstrated that the limit of detection was lowered 10-fold in an EIA employing the galactomannan monoclonal antibody as both captor and detector. Comparison with LA demonstrated improvement in both sensitivity and specificity (Verweij et al. 1995c). There is now a commercially available sandwich ELISA (Platalia Aspergillus, Bio-Rad Laboratories, Marnes La Coquette, France) with a reported sensitivity of 67–100 percent and specificity of 81–98 percent. Most importantly, this assay is sensitive enough to give positives at an early stage of the infection. Antigen titers increase in the terminal stages of the disease and serial assessment of serum titers is useful in monitoring response to treatment (Verweij et al. 1996, 1997). Prospective studies in patients with hematological malignancies have shown high sensitivity (>89 percent) and specificity (>92 percent) (Maertens et al. 1999, 2001; Sulahian et al. 2001). Sera were collected twice a week and a positive result reported when galactomannan was detected in two consecutive samples: increasing antigen titers in consecutive samples was a particularly strong indication of infection. These studies suggested that the cutoff value recommended by the manufacturer could be lowered. There is evidence that the test can be reliably applied to bronchoalveolar lavage and CSF specimens (Verweij et al. 1995a; Viscoli et al. 2002). The great majority of galactomannan in the CSF appeared to be produced intrathecally. The usefulness of monitoring response to treatment may vary with the drug used, since there is some data from a rabbit model of pulmonary aspergillosis to suggest that during treatment with the echinocandin caspofungin circulating antigen failed to decrease despite clinical improvement (Petraitiene et al. 2002).

Urine from recipients of bone marrow transplants with invasive aspergillosis contained not only galactomannan with a molecular weight of over 45 kDa but also several protein antigens between 11 and 44 kDa (Haynes et al. 1990). Other antigens described include an 80 kDa antigen (Phillips and Radigan 1989) and antigens at around 88, 40, 27, and 20 kDa (Yu et al. 1990). Burnie (1991b) developed a RPLA test detecting *Aspergillus* antigen with a rabbit polyclonal antiserum raised against a crushed extract of *A. fumigatus*. Antigen extracted from high-titer patient sera, by affinity chromatography using the same rabbit antiserum, reacted with monoclonal antibodies to *A. ambisexualis* and *C. albicans* Hsp90, showing that *Aspergillus* Hsp90 circulated during infection (Burnie and Matthews 1991).

PCR

In invasive aspergillosis, targets for PCR have been limited copy genes, for example the 18 kDa IgE-binding protein (Reddy et al. 1993) and alkaline protease (Tang et al. 1993), or multicopy genes such as the 26S intergenic spacer gene of rDNA (Spreadbury et al. 1993), the 18S rRNA genes (Yamakami et al. 1996), mitochondrial DNA (Jones et al. 1998), or panfungal targets such as the small subunit rRNA gene (van Burik et al. 1998). Specimens obtained at bronchoscopy have been tried, but the sensitivity can be low and false positives have been a persistent problem (Brètagne et al. 1995; Verweij et al. 1995a; Bart-Delabesse et al. 1996). This problem may be independent of the target sequence; it may be caused by colonization of the patient's respiratory tract or by contamination during processing.

Yamakami et al. (1996) developed an aspergillus-specific nested PCR, based on sequences derived from the 18S rRNA gene, which detected *Aspergillus* DNA in the sera of experimentally infected mice (sensitivity 71 percent) and 20 patients with invasive aspergillosis (sensitivity 70 percent). The same gene was targeted by Einsele et al. (1997), who detected circulating DNA in all 13 patients with invasive aspergillosis. Golbang et al. (1999) modified this assay to convert it from a nested PCR to a semiquantitative PCR-EIA, incorporating the digoxigenin label during the PCR and binding the amplicon to a streptavidin plate with a biotinylated capture probe. This assay was used to quantify the level of circulating DNA in invasive aspergillosis. The sensitivity was 91 percent, 30 of the 33 culture-confirmed cases of invasive aspergillosis giving positive optical densities (>0.1). It was negative in all 20 control sera. Where sequential samples were available, levels fell in survivors and gradually rose in fatal cases. PCR has also been successfully applied to cerebrospinal fluid specimens in cases of aspergillus meningitis (Kami et al. 1999; Verweij et al. 1999) and to ocular samples in fungal endophthalmitis (Jaeger et al. 2000). Comparative studies of the galactomannan ELISA with PCR have yielded conflicting results as to which is superior (Bretagne et al. 1998; Kawamura et al. 1999; Becker et al. 2000). Both systems have shown the ability to detect the infection early (Verweij et al. 1997; Hebart et al. 2000), opening up the possibility of prospective screening of high-risk patients and prompter treatment.

Real-time PCR greatly reduces the risk of false-positive results because the reaction tubes do not need to be opened following amplification, thus avoiding environmental contamination with the amplicon, the main source of contamination. Using the LightCycler, and a fully automated nucleic acid extraction technique to further reduce the risk of cross-contamination, Costa et al. (2002) compared the performance of real-time PCR with an ELISA for detecting galactomannan. They found serum to be preferable to white cells as a source

of *A. fumigatus* DNA. The galactomannan assay was more frequently positive than the PCR assay (52 percent versus 45 percent). It may be that *Aspergillus* releases large amounts of galactomannan, which is relatively easily detected compared to the tiny quantities of circulating fungal DNA, despite amplification by PCR. Even before death, the DNA concentration was never greater than 30 fg/ml of serum. More studies on the origins and kinetics of fungal DNA release would help resolve these issues.

CRYPTOCOCCOSIS

This systemic infection is caused by the encapsulated basidiomycetous yeast *Cryptococcus neoformans*. It can cause meningitis in non-immunocompromised patients, but the great majority of cases now occur in patients with the acquired immunodeficiency syndrome (AIDS), in whom it may present as meningitis, pneumonia, or fever resulting from an underlying cryptococcemia. Although the principles of laboratory diagnosis are the same, the lack of sufficient capsular material produced by some isolates from AIDS patients occasionally causes problems for standard LA tests.

Latex agglutination

Several latex agglutination tests (RPLA) are commercially available for the rapid detection of the capsular polysaccaride antigen. The capsular antigen is produced in large quantities, has a serum half-life of 24 hours (Kappe and Muller 1991), and is stable against heat or pronase treatment, allowing dissociation from bound antibodies. These RPLA tests, which use antibody-coated latex particles, are easy to perform and highly sensitive, and specific for the diagnosis of meningeal and disseminated cryptococcosis (Prevost and Newell 1978; Kauffman et al. 1981; Bhattacharjee et al. 1984). Although *C. neoformans* is usually easy to isolate from clinical material, it may take up to 10 days to appear. The RPLA test can give the diagnosis in 30 minutes. Titres of 1:100 or more can be demonstrated in the CSF and, particularly in AIDS patients, in serum. Antigen titers can help monitor response to therapy and give an indication of the extent of infection and, indirectly, of the prognosis. Antibody detection adds little (Hay 1992).

The sensitivity of RPLA tests is high, well above 90 percent. Reports as to the lower limits of detection with the Cryptococcal Antigen Latex Agglutination System (CALAS, Meridian Diagnostics Inc., Cincinnati, OH) and the Crypto-LA test (International Biological Labs Inc., Cranbury, NJ) are in the range 2.5–10 ng/ml of capsular polysaccharide for serotypes A–D (Temstet et al. 1992) and 7.6–61 ng/ml, the highest level being for serotype D (Gade et al. 1991). False positives can occur. A heat-stable cell wall component of *Trichosporon beigelii* (syn. *Trichosporon cutaneum*) crossreacts with cryptococcal polysaccharide (Melcher et al. 1991). Disseminated infections caused by *T. beigelii* can occur in immunosuppressed patients and they are a well-documented cause of positive results with cryptococcal RPLA tests (McManus et al. 1985). Other rare causes of false positives are malignancy (Hopfer et al. 1982) and septicemia with DF-2 (Westerink et al. 1987). Technical false positives have been reported as a result of the introduction of talc from latex gloves into CSF samples, following immersion of a platinum wire inoculating loop into a CSF sample for culture before testing, and after repeated washing of ring slides with certain disinfectants and soaps (Heelan et al. 1991; Blevins et al. 1995).

A prozone-like effect, probably the result of immune complex formation, can give rise to false negatives. This can be avoided by diluting out the specimen (Stamm and Polt 1980) or treating with pronase. Pronase considerably reduces the occurrence of false reactions by cleaving antibodies present in immune complexes, which can otherwise mask the detection of antigen, and destroying rheumatoid factor (Sadamoto et al. 1993). Pronase pretreatment is a recommended modification of many of the commercially available RPLA tests; it increases sensitivity for most sera and some (but not all) CSF samples, and improves the end-point readings by making the agglutination reactions stronger (Gray and Roberts 1988; J.R. Hamilton et al. 1991). Kohno et al. (1993) obtained significantly higher rates of detection of serum cryptococcal antigen using the Eiken test (Eiken Co., Tokyo) in conjunction with pronase pretreatment.

One of the commercially available LA tests (Pastorex *Cryptococcus*, BioRad, Marnes-La-Coquette, France) has a murine monoclonal antibody to cryptococcal polysaccharide (Dromer et al. 1987), sensitizing the latex particles instead of the more commonly used rabbit polyclonal antisera. Temstet et al. (1992) compared this with two commercially available RPLA tests using polyclonal immune sera, CALAS and Crypto-LA. Clinical specimens from 87 AIDS patients, 40 of whom had culture-proven cryptococcosis, were retrospectively tested in a blind study. Pastorex performed well during the initial screening, concordance among the three tests being 97 percent. The predominant serotypes were A and D, only one patient having serotype B and none having serotype C, which reflected the prevalent serotypes. However, the threshold for detection of capsular polysaccharide with Pastorex was at least a log poorer for serotypes B, C, and D, compared with CALAS and Crypto-LA. Pronase treatment enhanced both the sensitivity and specificity of Pastorex and it was recommended for all samples except urine. Interestingly pronase treatment did not resolve the prozone effect in one case which was corrected by sample dilution. The antigen titers obtained with Pastorex and CALAS after pronase treatment agreed within one dilution for 67 percent of CSF samples and 57 percent of sera. It was

emphasized, as previously observed (J.R. Hamilton et al. 1991), that kits for the detection of cryptococcal antigen cannot be used interchangeably to monitor antigen titres in patients.

Occasionally false negatives occur in AIDS patients as a result of a capsular-deficient variant of *C. neoformans*, resulting in low concentrations of the antigen. Both serum and CSF specimens are usually positive in AIDS patients with cryptococcal meningitis, definitive diagnosis then being made by culture of the CSF (Panther and Sande 1990). Routine screening for serum cryptococcal antigen does not, however, appear to predict patients who subsequently develop cryptococcal meningitis (Nelson et al. 1990). Localized pulmonary cryptococcosisis is likely to give negative RPLA results with serum samples (Prevost and Newell 1978; Kauffman et al. 1981), although Baughman et al. (1992) successfully screened specimens of bronchoalveolar lavage fluid with the CALAS test to diagnose cryptococcal pneumonia.

EIA

An EIA (Premier, Meridian Diagnostics), using a polyclonal capture system to bind capsular polysaccharide and visualized with a peroxidase-labelled monoclonal antibody, was compared with the CALAS RPLA by Gade et al. (1991). They obtained close agreement (98 percent). Overall sensitivity for the EIA was 99 percent and specificity 97 percent, there being 120 EIA and latex agglutination (LA) positives out of the 475 specimens screened. Detection limits for serotypes A–D were 0.63, 0.63, 7.8, and 62 ng/ml, respectively. Knight (1992) compared this with the RPLA test of Immuno-Mycologics and reported 92 percent agreement, after examination of 54 samples, mainly sera and CSF, from patients with and without cryptococcosis. There was some indication, but only in a couple of patients, that the EIA gave fewer false positives and improved the diagnosis of genuine early cases. The EIA test was easy to perform and had a similar cost. As a screening test it took no longer than the RPLA, although determining the titer of first time positives took longer.

Sekhon et al. (1993) compared the Premier EIA with two commercially available RPLA tests, Immuno-Mycologics and Crypto-LA, and a non-commercial latex agglutination test. Of 143 sera and CSF from proven and suspected cases, 115 were negative by EIA and RPLA. The sensitivity of the EIA test was 85.2 percent and specificity 97 percent, compared with 100 percent sensitivity and specificity for the LA tests. Out of 26 true-positive specimens, 23 were EIA positive but three RPLA positive specimens were negative by EIA. In the great majority of cases, however, the EIA yielded higher titers than the RPLA, especially for specimens from AIDS patients, observations similar to those made by Gade et al. (1991). They found the EIA, unlike RPLA, did not require pretreatment of specimens to prevent false-positive reactions.

An EIA has also been described by Casadevall et al. (1992), who used monoclonal antibodies, of different isotypes, both to capture and to detect cryptococcal polysaccharide. Immuno-Mycologics have produced a biotin-amplified sandwich EIA.

Noncapsular antigens

Chaturvedi et al. (2001) have cloned and compared the Cu, Zn superoxide dismutase gene from three varieties of *C. neoformans*, with variable host predilection, in order to provide insight into its role in pathogenesis. A.J. Hamilton et al. (1991) have produced a range of murine monoclonal antibodies which recognized culture filtrate antigens (exoantigens) from both encapsulated and non-encapsulated isolates of *C. neoformans*. This suggests that they did not recognize capsular polysaccharide material, and immunofluorescence data showed reactivity with the cytoplasm and cell membranes only. Some of these monoclonal antibodies crossreacted with *T. beigelii*. One monoclonal, which recognized neither *T. beigelii* nor *C. neoformans* var. *gattii*, recognized a species-specific epitope on a 34–38 kDa glycoprotein produced as an exoantigen by *C. neoformans* var. *neoformans* (Hamilton et al. 1992). Another monoclonal antibody recognized a 115 kDa exoantigen which has been shown to react strongly with the sera of patients with cryptococcosis (Hamilton and Goodley 1993). Monoclonal antibodies such as these may prove useful in the serodiagnosis of cryptococcosis in AIDS patients infected with isolates lacking polysaccharide capsules.

PCR

PCR has been successfully applied to the detection of *C. neoformans* in clinical specimens from confirmed cases (Rappelli et al. 1998; Posteraro et al. 2000), but whether it can outperform the exisiting, highly successful assays for this infection remains to be determined. Bialek et al. (2002c) have developed nested and real-time PCR assays, both targeting the 18S rRNA gene, to a murine model of cryptococcal meningitis.

HISTOPLASMOSIS

This is a systemic fungal infection caused by the dimorphic fungus *Histoplasma capsulatum*. The fungus is found in the soil and endemic to extensive parts of the Americas, Africa, and Asia. There are two varieties: the small-celled form (var. *capsulatum*), which occurs globally, and the large-celled form (var. *duboisii*), confined to Africa and Madagascar. Histoplasmosis is a common

and serious complication of AIDS, occurring with highest frequency in the endemic areas of the USA (Wheat et al. 1991). Infection usually begins in the lungs, but a progressive disseminated form of the disease often develops in AIDS patients. Clinical diagnosis may be hampered because the severity of the systemic disease overshadows the respiratory component and radiologically the chest may appear normal initially. Most of these patients present with fever and weight loss.

In exposed communities, up to 70 percent of the population have positive histoplasmin skin tests. The histoplasmin skin test is similar to the Mantoux test. It indicates exposure to the organism, and is used mainly for epidemiologic purposes. Many patients with disseminated infections are anergic and give negative skin tests whereas, in a sensitized individual, skin testing can induce antibodies which then complicate the serological diagnosis (Hay 1992; Kaufman 1992).

Laboratory diagnosis is required to confirm clinical and radiological signs of a systemic mycosis and to establish the etiology. Histopathological examination and culture of bone marrow biopsies and blood cultures are common means of obtaining a definitive diagnosis. But isolation and identification of the *capsulatum* variety of *H. capsulatum* from clinical material can take several weeks and requires conversion of the mycelial isolate to the yeast form or identification by commercially available exoantigen tests or DNA probes (Kaufman 1992; Huffnagle and Gander 1993). Therefore, serology is still the best method available for screening suspected cases of histoplasmosis.

Antibody assays

Proper interpretation of serology is helped by taking a full clinical history, including occupation, travel, residence, and whether the patient has undergone histoplasmin skin testing. The laboratory, which must be familiar with the tests' capabilities and limitations, can then select the appropriate battery of tests. Complement fixation (CF), ID, and LA tests for the detection of antibody are available commercially.

The histoplasmin LA test (available commercially from Immuno-Mycologics) detects IgM, which is produced in the early stages of infection. It is therefore only positive early in the course of a primary infection, becoming negative within the first few months of a chronic infection.

The ID test is based on the principles of double diffusion. The patient's serum and soluble antigen are placed in separate wells cut in a suitable diffusion medium (such as agarose or Cleargel) and allowed to diffuse outward. Visible lines of precipitate form where the antigen and antibody have combined in the proper relative concentrations (equivalence). Using the mycelial-form culture filtrate of *H. capsulatum* var. *capsulatum* as a source of H and M antigens ('histoplasmin'), both H and M precipitins are detected, the M precipitin band appearing nearer the antigen well. Positive control sera, containing specific antibodies against H and M antigens, are placed adjacent to each patient serum in order to determine the specificity of any patient reactions through the formation of an 'identity' or 'partial identity' reaction where the two precipitin bands interact.

The ID test detects IgG antibodies and is negative in the first 3–6 weeks of a primary infection when IgM predominates. It usually becomes positive within about 1 month of infection, but can remain completely negative in patients with confirmed histoplasmosis (Helner 1958). The M band is present in 70 percent of active cases (Kaufman 1992). Provided a skin test has not been performed recently (Kaufman 1973), it is an indicator of active infection or recent past infection, because M precipitins persist some months after recovery. The H band occurs less frequently than the M band, and the absence of an H band does not exclude active histoplasmosis. In active cases, 2 percent are H+ and 10 percent are H+ and M+ (Kaufman 1992). An H band usually indicates active clinical disease and, if both M and H precipitins are present, it is highly suggestive of active histoplasmosis regardless of other serological results. Demonstration of M and H precipitins in the CSF is indicative of meningeal histoplasmosis (Kaufman 1992).

The CF test is based on the principle that complement (C′) is irreversibly taken up by certain classes of antibody when they react with antigen, the presence of free C′ being indicated by lysis of sheep red blood cells sensitized with antibody because C′ is required for this process. If complement-fixing antibodies are present, there is no hemolysis. It is essential to determine serum anticomplementary activity. This is when the patient's serum fixes or destroys C′ in the absence of added antigen and can be caused by a number of factors. Other essential prerequisites include determination of the optimal antigen dilution with known case sera (not hyperimmune animal control sera), standardization of all reagents, and inclusion of positive and negative control sera.

The CF test is more sensitive than ID. Both histoplasmin (H and M), derived from the mycelial form of *H. capsulatum* var. *capsulatum*, and yeast form antigens are available commercially for use in CF tests. Leland et al. (1991) compared reagents from Immuno-Mycologics with those obtained from Meridian Diagnostics and found the former to be more reactive. Measurement of yeast antibody with the CF test has a higher sensitivity (90 percent) than histoplasmin antibody (80 percent) (Kaufman 1992). CF titers of more than 32, or a fourfold rise in titer, give good presumptive evidence of histoplasmosis. Lower titers are nonspecific, particularly with the yeast antibody. Skin testing may interfere with histoplasmin antibody, which can be induced or significantly

raised in histoplasmin-sensitized individuals after one histoplasmin skin test. Crossreactions can occur with sera from patients with blastomycosis, coccidioidomycosis, and other mycoses, and, with yeast-form antigen, they can occur in patients with leishmaniasis (Kaufman 1992). Lack of an antibody response should not exclude the diagnosis, particularly if only one specimen has been tested and the clinical picture is highly suggestive. CSF titers are usually 1:8 or greater in cases of meningeal histoplasmosis (Plouffe and Fass 1980).

Antibody assays are less reliable in immunocompromised patients and disseminated histoplasmosis. Torres et al. (1993) found that neither CF nor an EIA was useful for the diagnosis of disseminated histoplasmosis in AIDS patients. Kaufman (1992) found that the histoplasmin antigens used in CF and ID tests more readily detected histoplasmosis in AIDS patients than yeast form antigens.

Detection of antigens

A radioimmunoassay for detection of *H. capsulatum* var. *capsulatum* polysaccharide in urine or serum has been used successfully in the rapid diagnosis of disseminated (Wheat et al. 1989) and pulmonary (Wheat et al. 1992) histoplasmosis in AIDS patients. The antigen was found in the urine of 92 percent and serum of 88 percent of such AIDS patients. It could also be detected in the bronchoalveolar lavage fluid of 70 percent of cases, and was not detectable in negative controls. Wheat et al. (1991) found the assay particularly useful in the detection of relapses in AIDS patients with histoplasmosis. Antigen levels fell in response to antifungal therapy and an increase of more than 2 units in antigen levels during maintenance therapy was strongly indicative of relapse. They suggested routine measurement of antigen levels in both serum and urine every 1–3 months and in the event of clinical evidence of relapse. But in a comparative assessment of itraconazole versus fluconazole for the treatment of disseminated histoplasmosis in patients with AIDS, they found clearance of fungal blood cultures a better measure of antifungal effect than clearance of antigen (Wheat et al. 2002).

Other histoplasma antigens are now being characterized. Hamilton et al. (1990a) have immunological data suggesting that the M antigen of *H. capsulatum* var. *capsulatum* is a catalase. They have also produced monoclonal antibodies that distinguish between the varieties *capsulatum* and *duboisii*. These could be useful for epidemiology and serodiagnosis in areas where both these forms of histoplasmosis occur (Hamilton et al. 1990b). Torres et al. (1993) identified antibodies against four different antigens of *Histoplasma* spp. (91, 83, 70, and 38 kDa) by immunoblotting sera from patients with histoplasmosis. Gomez et al. (1992, 1995) have identified two heat-shock proteins, Hsp60 (HIS-62) and Hsp70 (HIS-80), mediating protective immunity against murine histoplasmosis through induction of cellular immunity. Maresca et al. (1994) have correlated the virulence of a strain with the time required to transform to the yeast form and to express heat shock genes. Detection of Hsp60 or Hsp70 in serum or urine could have diagnostic value for histoplasmosis analogous to the detection of Hsp90 in DC.

PCR

The detection of *H. capsulatum* in the soil currently involves a slow (6–8 weeks) and expensive assay requiring inoculation of mice. Therefore the development by Reid and Schafer (1999) of a 2-day PCR method, using fungal-specific primers followed by nested primers against an ITS region of a rRNA gene, should be a significant advantage. Bialek et al. (2002a) have developed a nested PCR assay to unambiguously identify *H. capsulatum* in tissue sections.

BLASTOMYCOSIS

This is caused by the dimorphic fungus, *Blastomyces dermatitidis*, endemic to parts of North America, Africa, India, and the Middle East. Diagnosis is usually made by the identification of the yeast in body fluids or tissues (such as sputa, bronchial lavage, or biopsy specimens) by potassium hydroxide smears, cytology, histology, or culture (Lemos et al. 2000; Martynowicz and Prakash 2002). As for histoplasmosis, serology can provide an indication of the likely diagnosis earlier than culture or histology. Serodiagnosis has improved following better purification of the A antigen of *B. dermatitidis*. Sensitivity varies, depending on the assay format, from 40 percent to 88 percent, but specificity is consistently very high (98–100 percent) (Kaufman 1992). Commercial sources include Immuno-Mycologics, Meridian Diagnostics, and Gibson Laboratories, Lexington, KY (formerly Nolan Scott Biological Laboratories, Atlanta, GA).

The widely used CF and ID tests, with purified A antigen, are only positive, respectively, in 40 percent and 65 percent of confirmed cases (Turner et al. 1986). Therefore a negative result in no way excludes active blastomycosis. The ID test is totally specific, an A band being presumptive evidence of active or recent infection. Sera from patients with other infections, such as histoplasmosis and coccidioidomycosis, may produce bands against the antigen to *B. dermatitidis*, but these do not form identity reactions with the A bands produced by the positive control serum.

More sensitive assay systems are now being developed. An indirect EIA, using purified A antigen, gave a sensitivity of 80 percent and a specificity of 98 percent (Turner et al. 1986). Titers of 1:32 or greater were indicative of

active blastomycosis while lower titers were considered suggestive but could be the result of crossreactivity with other dimorphic fungi, particularly the *capsulatum* variety of *H. capsulatum*. Lo and Notenboom (1990), using commercial A antigen captured with rabbit antibody to A antigen with a sandwich EIA, succeeded in avoiding crossreactivity with sera from patients with histoplasmosis or coccidioidomycosis. They detected seven of eight active cases of blastomycosis, compared with three positive cases by ID or CF. The false-negative result was from a patient with AIDS. A cell wall-derived radiolabelled 120 kDa protein has been used to detect antibody in infected patients by Klein and Jones (1990).

COCCIDIOIDOMYCOSIS

This systemic mycosis, caused by the dimorphic fungus *Coccidioides immitis*, generally takes the form of an acute, mild respiratory disease but can become chronic or disseminated, and occurs as an opportunistic infection in AIDS patients. The fungus is endemic only to certain semidesert-like regions between southwest USA and Argentina. Both clinical diagnosis and laboratory diagnosis, by demonstration of the organism histologically or by culture, are sometimes difficult. Often positive serology is the first evidence of the diagnosis, indicating the need for more definitive techniques which may require biopsy.

Serodiagnosis is generally based on the detection of antibodies to two main antigens to *C. immitis*: the tube precipitin (TP) and CF antigens found in mycelial-form culture filtrate (coccidioidin). Antibody to the former was thought to be mainly IgM, although recent data suggest that IgG responses are often largely directed against TP (Gade et al. 1992). Antibody to CF antigens is mainly IgG (Pappagianis and Zimmer 1990). The early IgM response is useful in the diagnosis of acute primary coccidioidomycosis. Later, IgG is produced, usually outlasting the IgM, and persisting in chronic coccidioidomycosis.

Partial characterization of both TP and CF antigens has occurred. Both 120 kDa and 110 kDa components of TP have been identified as a glycoprotein co-localized within cytoplasmic vesicles and the wall of the spherule (Cole et al. 1991). Deglycosylation of these antigens resulted in significant loss of reactivity with patient IgM. Although mannose and glucose were the predominant monosaccharides, a 3-*O*-methylmannose sugar is also present which appears to be unique to this systemic fungal pathogen and at least partially responsible for the reactivity of IgM with the 120 kDa antigen. One of the CF antigens, which participates in the ID reaction, appears to be a chitinase (Johnson and Pappagianis 1992).

A LA test is commercially available (Immuno-Mycologics). It uses TP-coated latex particles to detect agglutinating antibodies. These are primarily IgM, but high titers of IgG can also cause agglutination (Martins et al. 1995a). It is a sensitive and simple rapid screening test, useful in detecting early acute disease, but it has a high rate of false positives so confirmation by ID is essential (Drutz and Cantanzaro 1978). Rheumatoid factor is one cause of false positives and should be excluded. It can be removed by IgG-absorbent diluents and columns that leave the IgM intact (Martins et al. 1995b).

The ID test can be used to detect antibodies to TP or CF antigens. The immunodiffusion tube precipitin (IDTP) test, thought to measure IgM, is a sensitive and specific indicator of early acute disease (Pappagianis and Zimmer 1990; Kaufman 1992). IgG is detectable by immunodiffusion complement fixation (IDCF) or CF tests and is useful in diagnosing later stages of infection. It can also be used to detect past infection. Quantification of antibody titers provides an indicator of disease progression, falling titers being a measure of response to therapy. Changing or high CF titers are diagnostic (Kaufman 1992). Lower CF titers may reflect crossreactivity and such results should be confirmed by IDCF. The IDCF test can be used as a qualitative screen or it may be quantified. CF and IDCF can be applied to serum or CSF samples.

An EIA for the detection of IgM and IgG against a purified mixture of TP and CF is now commercially available from Meridian Diagnostics (Gade et al. 1992). In assessing this assay, Martins et al. (1995a) compared the IgM EIA with LA, and the IgG EIA with ID and CF tests. It proved to be a reliable assay for the detection of antibodies in serum or CSF against both TP and CF antigens. The best overall correlation was achieved when EIA was compared with the combined results of the traditional assays; there was an agreement of 96.7 percent, a specificity of 98.5 percent and a sensitivity of 94.8 percent. EIA had several advantages. It used specific anti-IgG and anti-IgM conjugates to give a definitive IgG or IgM result. Results were determined objectively with a spectrophotometer. Unlike the CF test, indeterminate results caused by anticomplementary activity were not a problem, and there was no need to heat inactivate the specimen or for an overnight incubation. The EIA could be run in less than 2 hours, allowing results to be reported the same day the sample was received. A disadvantage of the EIA was that because the same serum dilution was used for both IgG and IgM testing, there was no IgG absorbent in the diluent; samples positive for specific IgM must therefore be tested for rheumatoid factor.

PARACOCCIDIOIDOMYCOSIS

This systemic mycosis, caused by the dimorphic fungus *Paracoccidioides brasiliensis*, is endemic to Latin America. It primarily involves the lungs but may disseminate, causing secondary lesions. Definitive diagnosis

can only be achieved using laboratory procedures such as microscopy, histology, and culture.

Many different tests have been used for the serodiagnosis of paracoccidioidomycosis. A comparative assessment including ID, CIE, and CF tests was reported by Del Negro et al. (1991). The ID and CIE tests with yeast culture filtrate were the most sensitive (91.3 percent and 95.6 percent, respectively) and highly specific (100 percent), significantly outperforming the CF test. A positive ID result is, therefore, taken as presumptive evidence of current or recent infection. The ID test is commercially available for research use from Immuno-Mycologics. Most frequently a single E band (also called band 1) is produced, but sometimes two additional bands are present. The greatest limitation of the test is seen with specimens from patients with early primary infections. During the first 4–8 weeks, IgM antibodies predominate and these react poorly in gel diffusion tests, because of their large size. In disseminated disease, CF antibody titers are high, usually falling with successful therapy and rising with relapses, but not uncommonly titers of 8–32 persist even after successful therapy (Restrepo et al. 1978). Do Valle et al. (2001) found immunoblotting gave better results than double immunodiffusion, raising sensitivity to 100 percent. Costa et al. (2000) improved the diagnostic coverage of ID from 93–95 percent, using crude antigens, to 100 percent in an enzyme-linked ID assay capture test using the gp43 antigen described below. Mamoni et al. (2001) developed a capture ELISA to detect specific IgE, the levels of which correlated with clinical severity, falling with clinical improvement. In conclusion, measurement of antibody is useful for both diagnosis and prognosis.

Detection of circulating *P. brasiliensis* antigens could facilitate early diagnosis or confirm a preliminary diagnosis when antibody assays are inconclusive. Several techniques with different sensitivities have been used (Brummer et al. 1993; Mendes-Giannini et al. 1993). Mendes-Giannini et al. (1989) identified a circulating 43 kDa glycoprotein, gp43, in the sera of both acute and chronic cases. This shared epitopes with Fava-Netto's (1990) cytoplasmic polysaccharide antigen (FNPA), another antigen widely used diagnostically (Rodrigues and Travassos 1994). The gp43 antigen has now been cloned and expressed in *Escherichia coli* (Diniz et al. 2002). Taborda and Camargo (1993, 1994) have developed both a passive hemagglutination assay and a dot immunobinding assay, based on detection of antibody to gp43, for the diagnosis of paracoccidioidomycosis.

Two heat-shock proteins, Hsp60 and Hsp87, have been characterized. The 87 kDa antigen was detected in infected patients' sera, its levels correlating well with response to treatment and clinical cure. Direct amino acid sequencing revealed substantial homology with heat-shock proteins and immunological crossreactivity with a monoclonal antibody against *H. capsulatum* Hsp80 (Diez et al. 2002). A monoclonal antibody to this 87 kDa antigen demonstrated that the level of expression was higher in the yeast than the mycelial phase and that the yeasts expressed the antigen in tissues from infected patients. The Hsp60 gene from *P. brasiliensis* has been cloned and characterized; both the recombinant protein and Hsp60 extracted from the yeast reacted with sera from infected patients (Izacc et al. 2001). Immunoblots of the recombinant protein indicated reactivity with 72 of 75 sera from paracoccidioidomycosis patients (Cunha et al. 2002); there was also some reactivity with sera from healthy controls (9.5 percent) and patients with histoplasmosis (11.5 percent).

Bialek et al. (2000b) developed a nested PCR directed against an outer-membrane protein gene unique to *P. brasiliensis*, and successfully used it to detect the fungus in tissue samples from a mouse model of the infection. Gomes et al. (2000) have a PCR assay based on the gene sequence of the gp43 antigen. Others have sequenced rDNA genes and intergenic spacers to derive primers capable of discriminating *P. brasiliensis* from other human fungal pathogens by PCR (Motoyama et al. 2000). Sano et al. (2001) have applied nested PCRs based on both the gp43 gene and the 5.8S ribosomal RNA gene to infected murine tissues. These early developments may well evolve into PCR-based assays useful in the diagnosis of this infection.

Histopathological diagnosis of mycotic diseases

HENRIK ELVANG JENSEN AND FRANCIS W. CHANDLER

Introduction	1	Diagnostic application of immunohistochemical techniques	10
Histological stains for demonstrating fungi	2	Special terminology	12
Histopathological identification of fungi	5	Figures	12
		References	22

INTRODUCTION

Ideally, diagnosis of a fungal pathogen is made by observation of typical clinical symptoms, by demonstration of the presence of a fungus within lesions accompanied by a host reaction, and by subsequent isolation in culture of the infectious agent. Unfortunately, this has been achieved comparatively rarely in certain deep mycoses. Moreover, patients with fungal infections are frequently also suffering from other diseases, which may mask the fungal-related symptoms. As a result of the nonspecific nature of the clinical observations including radiological findings in fungal infections, a diagnosis usually depends on several laboratory approaches apart from mycological culture and histopathology. These include detection of:

- fungal antigens in serum, spinal fluid, bronchoalveolar lavage specimens, and urine as, for example, *Histoplasma* antigen, cryptococcal antigen, and galactomannan in cases of aspergillosis
- antifungal antibodies useful in, for example, histoplasmosis
- fungal metabolites such as D-arabinitol in *Candida* infections
- cell wall markers like (1→3)-β-D-glucan which is present in the wall of almost all fungi with the exception of zygomycetes (Reiss et al. 2000).

In recent years, molecular-based techniques such as the polymerase chain reaction (PCR) have been developed for the non-culture based diagnosis of fungal infections in blood and other clinical specimens. Due to the risk of false-negative and false-positive results in both culture- and nonculture-based diagnostic tests for mycotic infections, clinical features should always complement histopathology in the diagnosis of fungal infections.

Many of the nonculture-based techniques are not available for many of the unusual mycotic pathogens. Isolation of fungi from tissues is often also problematic. Culture of fungi is often a slow process, and results may not be available for several days or weeks. Moreover, when a mycosis is not suspected (often they are mistaken for neoplasms or inflammation of unknown etiology), the whole biopsy specimen is often fixed for histopathological examination, and thus portions are not available for culture (Jensen 1994). When this occurs, histopathological and immunohistological techniques may be the only means of establishing an etiologic diagnosis short of repeating the biopsy procedure. A systematic approach must then be taken to arrive at the most accurate diagnosis possible by examining fixed, paraffin-embedded tissue sections. Although the morphology of fungal elements within tissues may provide a tentative diagnosis, it is not always possible to establish a clearcut diagnosis based on morphological details because of morphological similarities among tissue forms of several fungal genera and the presence of sparse or atypical fungal elements (Chandler et al. 1980; Jensen et al. 1996).

Histopathological studies can contribute in a variety of ways to the diagnosis of diseases caused by fungi and related pathogens. A generic or specific etiologic

diagnosis may be made in 24 hours or less by the unequivocal demonstration and identification of characteristic fungal elements in tissue sections (Baker 1971; Anthony 1973; Schwarz 1982). Direct microscopic examination is the only reliable way of diagnosing certain fungal diseases, such as lobomycosis, rhinosporidiosis, and *Pneumocystis* infections, for which isolation techniques do not currently exist. The etiologic significance of a culture isolate can usually be determined by careful histopathological evaluation (Chandler and Watts 1987). Microscopic demonstration of tissue invasion and host reaction resolve the clinical dilemma of whether a fungal isolate is truly pathogenic, or merely a superficial colonizer, a component of the normal mycobiota (e.g. *Candida albicans*), or an environmental contaminant (e.g. a species of *Aspergillus* or a member of the class Zygomycetes) (Hoog and de Guého 1985). Microscopic evaluation of the inflammatory reaction and the distribution of fungal elements in a tissue section can also help to determine whether the disease is an invasive infection or a purely allergic reaction (e.g. invasive versus allergic bronchopulmonary aspergillosis); it can sometimes be used to assess the efficacy of antifungal therapy in pre- and post-treatment biopsy specimens (Chandler and Watts 1987). Finally, histopathological studies may sometimes confirm the presence of multiple infections, e.g. in acquired immunodeficiency syndrome (AIDS), or exclude a fungal disease from the clinical differential diagnosis altogether by revealing another process that accounts for the clinical and radiological findings. Accurate diagnosis may not only give the benefit of optimal therapy, but is also essential for the study of the pathological and epidemiologic aspects of different mycoses (Jensen 1994).

HISTOLOGICAL STAINS FOR DEMONSTRATING FUNGI

A number of traditional histochemical stains can be used to detect fungi and related pathogens in tissue sections. These stains, along with their applications and limitations, are summarized in Table 1. Details of the staining procedures are not included here, but can be found in standard manuals and textbooks (Elias 1982; Bancroft and Stevens 1996) of histochemistry and histological techniques.

Hematoxylin and eosin (H&E) is a versatile stain which enables pathologists to evaluate the host's inflammatory response, including the Splendore–Hoeppli (asteroid bodies) reaction, and to determine whether a fungus is hyaline (colorless) or pheoid (naturally pigmented–dematiaceous) (Matsumoto et al. 1994). It is the histological stain of choice to demonstrate the hematoxylinophilic or amphophilic nuclei of yeast-form cells that are multinucleated, particularly those of *Blastomyces dermatitidis*, *Loboa loboi*, and *Paracoccidioides brasiliensis*. Some fungi, e.g. the aspergilli and zygomycetes, are hematoxylinophilic and readily delineated with H&E, but many fungal agents are not stained or stain poorly. Even in the instances of poor staining, careful examination often reveals the outlines of unstained fungal elements, which suggest the existence of a fungal infection. Moreover, pathologists should always pay special attention to and carefully search for fungal elements when a granulomatous or pyogranulomatous inflammation is present (Jensen 1994). The H&E procedure has limitations, however. With this stain, it is sometimes difficult to distinguish fungal elements from tissue components, e.g. thin blood vessels within brain and lung tissues, and, when fungi are sparse, they are easily overlooked (Jensen et al. 1997). As a result of these limitations, special stains for fungi are usually needed to adequately reveal the presence and morphology of fungal pathogens in tissue sections (Chandler and Watts 1987).

Special histological stains such as Gomori's methenamine silver (GMS), the periodic acid–Schiff (PAS) reaction, and Gridley's fungus (GF) procedures are useful to demonstrate fungi in tissue sections. The staining reactions of these procedures are based on the principle that adjacent hydroxyl groups of complex polysaccharides in fungal cell walls are oxidized to aldehydes by chromic acid or periodic acid. In the GMS procedure, the aldehydes reduce the methenamine silver nitrate complex; fungal cell walls stain brownish–black because reduced silver is deposited wherever aldehydes are located. In the PAS and GF procedures, the aldehydes react with Schiff's reagent, coloring fungi magenta. All three procedures stain the cell walls of fungal elements, but tend to obscure the internal details of these cells. Moreover, hydroxyl groups in tissue elements such as basement membranes will also be stained by these techniques. The GMS stain is the best procedure for detecting fungi in tissue sections because it provides better contrast for screening and, in most instances, it will stain old and nonviable organisms that may be refractory to the PAS and GF procedures. Fungi stained with the last-mentioned procedures also tend to fade with prolonged storage. When properly done, the GMS procedure usually eliminates nonspecific background staining of normal tissue components and necrotic debris, whereas the PAS and GF procedures do not. The GMS stain is also more sensitive because it demonstrates certain nonfungal pathogens, e.g. *Actinomyces israelii* and related species, *Nocardia* spp., *Mycobacterium* spp., nonfilamentous bacteria with polysaccharide capsules, and free-living soil amoebae, algal cells, spores of microsporidians, and cytoplasmic granular inclusion bodies of cytomegalovirus (Chandler and Watts 1987). Such an all-purpose, low-specificity stain is extremely helpful for the rapid screening of specimens from immunocompromised patients, who are often infected by multiple pathogens.

When performing the GMS stain, the histotechnologist should vary the staining time according to the etiologic agent under consideration, guided by a

Table 1 *Stains for demonstrating fungi and related pathogens in tissue sections*

Stains	Applications	Limitations
Hematoxylin and eosin (H&E)	Demonstrates inflammatory response Stains some fungi Allows determination of innate color of pheoid (pigmented) fungi Demonstrates Splendore–Hoeppli material Hematoxylin stains nuclei of most yeast-like cells	Does not stain many fungi Inadequate to screen for sparse fungal elements Does not stain individual filaments of *Actinomyces*, *Nocardia* and *Streptomyces* spp.
Special stains for fungi	All three stains are excellent for detecting fungi	Do not allow determination of the innate color of a fungus (GMS stains fungi black–brown; GF and PAS stain fungi red–purple, which mask innate color)
Gomori's methenamine silver (GMS)	The GMS is better than GF or PAS for screening; it stains old and nonviable fungal elements better than the other two stains, and it also demonstrates filaments of *Actinomyces* spp. and *Nocardia* spp. and elements of *Pneumocystis carinii*	GMS may overstain fungi and obscure internal details
Gridley's fungus (GF)		GMS and GF do not allow proper study of host response
Periodic acid–Schiff (PAS)		GF and PAS do not stain filaments of the actinomycetes
GMS with H&E counterstain	Permits study of host response and is excellent for detecting fungi and most actinomycetes The stain of choice, if only one slide is available for histopathological evaluation Excellent for photomicrography	Does not allow determination of the innate color of phaeoid (pigmented) fungi
Mucin stains		
Mayer's mucicarmine	Stain mucopolysaccharide capsular material of *Cryptococcus neoformans*	Not specific for *Cryptococcus neoformans* (may stain *Rhinosporidium seeberi* and some cells of *Blastomyces dermatitidis*)
Southgate's mucicarmine Alcian blue	Permit differentiation of *C. neoformans*, from other fungi of similar size and form	
Modified Gram's stains		
Brown and Brenn	Demonstrate gram-positive filaments of *Actinomyces* spp., *Nocardia* spp. and other actinomycetes	Do not selectively stain most fungi (those that do stain are gram positive)
Brown–Hopps	Useful for detecting bacterial copathogens	
MacCallum–Goodpasture	Demonstrate gram-positive and gram-negative bacteria of botryomycosis	
Modified acid-fast stains		
Modified Ziehl–Neelsen	Useful to detect *Nocardia asteroides*, *N. brasiliensis*, and *N. otitidiscaviarum*	*Nocardia* spp. are weakly acid-fast and non-alcohol-fast in tissue sections
Fite–Faraco Kinyoun's	Valuable to detect *Mycobacterium tuberculosis* and other mycobacteria	Fungal cell walls and the agents of actinomycosis are not acid-fast
Melanin stain		
Modified Fontana–Masson	Stains cell walls of *Cryptococcus neoformans* and other *Cryptococcus* spp. Accentuates melanin or melanin-like substances in weakly pigmented agents of pheohyphomycosis	May stain cell walls of *Sporothrix schenckii* and immature spherules of *Coccidioides immitis*
Whitening agents		
Calcofluor White M2R, Blankophor, Uvitex 2B and others	Stain cell walls of most fungi	Require a fluorescence microscope Do not consistently stain fungal elements May not stain degenerated fungi

concurrently stained positive control slide. To accomplish this, the control slide should be periodically removed from the silver nitrate bath and examined under a light microscope for optimal staining. Optimal staining time in the silver nitrate solution is usually increased when old, degenerated, and nonviable fungal elements are suspected, such as those of *Coccidioides immitis* and *Histoplasma capsulatum* var. *capsulatum* in the caseated centers of residual granulomas. The depth of staining should never be so intense that it obscures the morphological details of fungal elements; preferably, some internal (cytoplasmic and nuclear) details should remain visible. When a tissue section is overstained with GMS, the contrast between fungal cells and background tissue elements is obscured. Blood vessels with darkened basement membranes can mimic fungal hyphae, particularly if the vessels are empty, branched, and of approximately the same caliber as the suspected fungus. Erythrocytes, leukocytes, and naked nuclei can be overstained and mimic yeast cells, whereas darkened reticular and elastic fibers can be mistaken for filamentous fungi or bacteria. In caseated granulomas, calcific bodies that stain with H&E and PAS procedures often simulate yeast cells, particularly those of *Cryptococcus neoformans* and *H. capsulatum* var. *capsulatum*. As the chromic acid used as an oxidant in the GMS and GF procedures dissolves calcium, calcific bodies are unstained when these procedures are used to confirm the presence of a fungal pathogen (Chandler and Watts 1987).

A major disadvantage of special stains is that they mask the innate color of fungal elements, making it impossible to determine whether a fungus is hyaline or pheoid. Such a determination may be crucial to the diagnosis of a mycosis caused by pigmented fungi, e.g. pheohyphomycosis, chromoblastomycosis, and black-grain eumycotic mycetomas (Chandler and Watts 1987). As a result of masking, duplicate H&E-stained or unstained tissue sections should always be examined to look for brown pigmentation of fungal cell walls. Another limitation of the special stains for fungi is that they do not allow adequate study of the host reaction to fungal invasion. To avoid this limitation, H&E can be used as the counterstain for the GMS procedure. This combination of stains (GMS–H&E) readily colors fungal elements brownish–black while staining background tissue components as expected. Thus, it is possible simultaneously to detect the fungus and to evaluate the host's inflammatory response and its relationship to the fungus. Tissue sections stained with GMS–H&E are also optimal for photomicrography.

When only a single unstained section from a suspected lesion is available for examination, GMS–H&E is the best stain combination for attempting to make a diagnosis. If desired, the section can be stained initially with H&E, checked for the presence of pheoid fungi, and then restained with GMS–H&E. For retrospective studies of unexplained lesions, tissue sections previously stained with Giemsa, modified Gram's, PAS, and GF procedures can be decolorized in acid alcohol after the coverslip has been removed and then restained with GMS.

Stains for mucin, such as Alcian blue and Mayer's or Southgate's mucicarmine procedures, readily demonstrate the mucopolysaccharide capsule of *Cryptococcus neoformans*. This staining reaction is a convenient diagnostic marker and usually differentiates typical cryptococci from nonencapsulated yeast-form pathogens of similar size and appearance. In rare cases, however, capsule-deficient cryptococci may not stain positively for mucin. In addition, mucin stains are not specific for *C. neoformans*, because the cell walls of *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, and *Rhinosporidium seeberi* are also variably colored with these stains. As the last three fungi are nonencapsulated and morphologically distinctive, ordinarily they would not be mistaken for *C. neoformans*. Mucin stains are not required for their identification.

The cell walls of cryptococci contain silver-reducing substances (melanin-like substances derived from dihydroxyphenylalanine), which react positively with a modified Fontana–Masson stain for melanin (Kwon-Chung et al. 1981; Wheeler and Bell 1987; Dixon and Polak 1991). As this stain reaction does not depend on the presence of a mucinous capsule, it can be used routinely to demonstrate capsule-deficient cryptococci (so-called 'dry' variants) (Ro et al. 1987). Capsule-deficient cryptococci stained with conventional procedures can easily be confused with nonencapsulated yeasts of similar size and morphology. When the agents of pheohyphomycosis are either nonpigmented or lightly pigmented in tissue sections, stains for melanin can also be used to accentuate and confirm the presence of melanin in their cell walls (Wood and Russel-Bell 1983; Chandler and Watts 1987). Studies have shown that the pigment in many of these fungi is a particular type of melanin derived from dihydroxynaphthalene, which differs from the melanin produced by *C. neoformans* (Dixon et al. 1991).

Modified Gram's stains, such as the Brown and Brenn and MacCallum–Goodpasture procedures, demonstrate the delicate, branched, gram-positive filaments of the agents of actinomycosis, nocardiosis, streptomycosis, dermatophilosis, and actinomycotic mycetomas. The GMS procedure can also be used to demonstrate these agents, but they often do not stain intensely or uniformly. The H&E, PAS, and Gridley procedures do not stain the actinomycetes (although entire granules in actinomycosis and actinomycotic mycetomas stain well, individual filaments within the granules are unstained). Modified Gram's stains are also needed to detect bacteria other than actinomycetes that may complicate a mycotic or actinomycotic infection, or that might be the primary cause of disease, e.g. botryomycosis (Chandler and Watts 1987). Some fungi, especially the yeast forms of *Candida* spp. and the conidia of *Aspergillus* spp. are usually gram-positive. Gram's stains are not, however,

recommended for screening or for definitive diagnosis of mycoses caused by these agents.

As the *Nocardia* spp. are weakly acid-fast and non-alcohol-fast in tissue sections, these filamentous bacteria can be distinguished from the agents of actinomycosis with modified acid-fast stains that use a weak aqueous solution consisting of 0.5 or 1.0 percent sulfuric acid for decolorization; the nocardiae are weakly acid-fast, whereas the agents of actinomycosis are not acid-fast. The cytoplasm of certain fungi with yeast-like tissue forms, especially *B. dermatitidis* and *H. capsulatum* var. *capsulatum*, is also variably acid-fast (Wages and Wear 1982). The acid-fast properties of fungi are, however, inconsistent and should not be depended on for diagnosis. The cell walls of fungi are not acid-fast.

When H&E-stained tissue sections that contain fungi are examined under ultraviolet light, some of the fungal elements usually autofluoresce (Graham 1983). Although this property may help delineate sparse or poorly stained fungi, fungal autofluorescence is inconsistent and should not be used as a substitute for the more reliable special stains such as GMS or for immunohistological procedures. Some fungi in paraffin-embedded or fresh-frozen tissue sections also stain nonspecifically with optical brightening histochemistry, i.e. whitening agents that have a diaminostilbene backbone structure, such as Calcofluor White M2R, Blankophor, and Uvitex 2B, which fluoresce under ultraviolet light (Monheit et al. 1984, 1986; Jensen 1994). Most of these fluorescent brighteners have an affinity for certain glycosidic linkages of the polysaccharides of the fungal cell wall. Tissue sections are usually stained for one minute with a 0.1 percent solution of the whitening agent, counterstained with Evan's blue, and examined with a fluorescence microscope with an excitation band of 500 nm. This rapid and simple procedure has been used in the intraoperative examination of fresh-frozen tissues for fungi, scrapings, swabs, and body fluids. Whitening agents, however, do not always highlight fungi, and these compounds should only be used for definitive diagnosis when positive. There is no advantage in using whitening agents compared with the rapid methenamine silver techniques for the detection of fungi in tissue sections (Shimono and Harman 1986).

HISTOPATHOLOGICAL IDENTIFICATION OF FUNGI

As a result of their large size, polysaccharide content, and morphological diversity, fungi can be detected readily and may also to a certain level be identified in histological sections by conventional light microscopy (Schwarz 1982; Salfelder 1990). Fungal elements in tissue sections are either hyaline or pheoid, and usually appear as yeast-like cells, hyphae, endosporulating spherules, granules, or a combination of these forms. These four broad morphological categories form a useful nontaxonomic system to approach the histopathological differential diagnosis of fungal diseases. Once a pathogen is correctly recognized as belonging to one of the four categories, it can in many cases be accurately identified to the level of genus or even to the species level by further consideration of its defining morphological and tinctorial features. For example, within the broad category of yeast-like pathogens, further defining features would include:

- size and shape of individual cells
- thickness of the cell wall
- number and shape of blastoconidia (buds)
- type of attachment of buds to parent cells
- presence or absence of septations
- pigmentation
- encapsulation
- number of nuclei
- presence of pseudohyphae, hyphae or arthroconidia.

Thus, a yeast-like pathogen with a thick cell wall, single broad-based bud, and multiple nuclei can only be *B. dermatitidis*. An encapsulated yeast-like pathogen can only be a *Cryptococcus* sp. A pathogen that forms budding yeast-like cells, pseudohyphae, and hyphae, but not arthroconidia, and is not pheoid (naturally pigmented), can only be a *Candida* sp. The system is less reliable for the category of pathogens with hyphal tissue forms, many of which appear quite similar. Moreover, the appearances of hyphae in sections are often affected by steric orientation, age of the hyphae, type of infected tissue, and the host response (Jensen and Schønheyder 1989). The morphological and tinctorial features of fungi that occur in tissue as yeast-like cells, large spherules, and nonpigmented hyphae are summarized in Tables 2, 3 and 4.

In the practice of surgical pathology, a specific etiologic or generic diagnosis of a fungal infection often has important prognostic and therapeutic implications. Certain fungal diseases are caused by agents that can be specifically identified in tissue sections because they are morphologically distinctive. In this group, a single species or variety of fungi is usually responsible for each particular disease, and if sufficient numbers of typical organisms are demonstrated, an etiologic diagnosis can be made. This group of diseases includes adiaspiromycosis, blastomycosis, coccidioidomycosis, cryptococcosis, small and large form histoplasmosis, lobomycosis, paracoccidioidomycosis, infection due to *Penicillium marneffei*, rhinosporidiosis, sporotrichosis, and pneumocystosis. Other fungal diseases are caused by any of several members of a genus that, in tissues, are all morphologically similar to each other. Typical forms of these fungi also have a distinctive morphology but can only be identified to the genus level. Diseases caused by fungi in this group, which can be diagnosed generically, include candidosis and trichosporonosis. Table 4 clearly shows that agents of aspergillosis, fusariosis and scedosporiosis most often cannot be separated in tissue

Table 2 *Morphological features of fungi that occur as yeast-like cells in tissue*

Feature	*Histoplasma capsulatum* var. *capsulatum*	*Histoplasma capsulatum* var. *duboisii*	*Blastomyces dermatitidis*	*Cryptococcus neoformans*	*Penicillium marneffei*	*Paracoccidioides brasiliensis*	*Loboa loboi*	*Sporothrix schenckii* var. *schenckii*[d]	*Candida* spp.	*Candida glabrata*	*Pneumocystis carinii*
Size (μm)	2–4	6–12	7–15[a]	2–20	2.5–5	5–60	5–12	2–10	3–6	2–5	2-10
Shape	Spherical or oval	Oval	Spherical	Pleomorphic	Spherical, oval or elongated	Spherical	Spherical	Pleomorphic[e]	Spherical or oval	Spherical or oval	Spherical, oval or crescentic
Number of buds	Single	Single	Single	Single and rarely multiple	None	Multiple; 'steering wheel' forms	Multiple; chains	Single and rarely multiple	Single; chains	Single	None
Attachment of buds	Narrow	Narrow	Very broad	Narrow	NA[c]	Narrow	Narrow; tubular	Narrow	Narrow	Narrow	NA[c]
Schizogony	–	–	–	–	+	–	–	–	–	–	+
Thickness of cell wall	Thin	Thick	Thick	Thin	Thin	Variable	Thick	Thin	Thin	Thin	Thick in 'cysts'; thin in 'trophozoites'
Pseudohyphae and/or hyphae	Rare	Absent	Rare	Rare	Absent	Rare	Absent	Rare	Characteristic	Absent	Absent
Number of nuclei	Single	Single	Multiple	Single	Single	Multiple	Multiple	Single	Single	Single	Multiple in 'cysts'; single in 'trophozoites'
Mucicarmine reaction	–	–	±	+[b]	–	±	–	–	–	–	–

a) Microforms, 2–4 μm in diameter, also may occur in tissue.
b) Some strains may be capsule deficient and noncarminophilic.
c) NA, not applicable.
d) The cells of *S. schenckii* var. *luriei* are larger (10–20 μm) compared with the var. *schenckii*, and typical 'eyeglass' forms are often seen.
e) Elongated, cigar-shaped cells characteristic but infrequent.

Table 3 *Morphological features of fungi that occur as large spherules in tissue*

Feature	*Coccidioides immitis*	*Rhinosporidium seeberi*	*Chrysosporium parvum* var. *crescens*
External diameter of spherule (μm)	20–200	100–350	200–400
Thickness of spherule wall (μm)	1–2	3–5	20–70
Diameter of endospores	2–5	6–10	None
Hyphae or arthroconidia	Rare	None	None
Special stain reactions			
GMS	+	+	+

sections (Jensen et al. 1996). Moreover, aspergillosis, fusariosis and scedosporiosis may in some cases also be confused with zygomycosis and candidosis, respectively (Jensen et al. 1997). In especially chronic lesions with atypical fungal forms, similar problems do also apply to a number of other fungi that belong to different genera but appear morphologically similar to each other in tissue sections. Although the etiologic agent in some lesions cannot be specifically or generically identified, the disease can still be named, i.e. chromoblastomycosis, dermatophytosis, hyalohyphomycosis, pheohyphomycosis, and zygomycosis.

In organs with access to air, especially within the upper parts of the respiratory tract, but also within the lungs, conidial heads are sometimes formed. The morphology of such frutification bodies may sometimes allow an identification of the infecting agent to the species level (Salfelder 1990). Heavy deposits of birefringent calcium oxalate crystals in tissues may also be used to sustain the identification of *Aspergillus niger* (Salfelder 1990). In other cases, *A. niger* infections may result in the developing of generalized oxalosis (Salfelder 1990).

Mycetomas constitute special cases. By studying the granules – the diagnostic hallmark of the mycetomas – in appropriately stained sections of infected tissue, one can easily determine whether the etiologic agent is an actinomycete (branched, filamentous bacterium) or a eumycete (true fungus), and, if a eumycete, whether it is hyaline (white grained) or pheoid (black grained). The size, shape, color, and microscopic architecture of the granules are correlated with the etiologic agent, and each species, with some exceptions, forms its own distinctive type of granule (Chandler and Watts 1987). Thus, the gross and microscopic appearances of the granules provide insight into the identity of the organisms involved. Definitive identification of the etiologic agents should, however, be based, whenever possible, on microbiological culture.

Finally, in some cases, intact fungal elements or fragments may be detected in tissue sections but cannot be definitively or even presumptively identified. In other cases, the morphology of fungi may be atypical or bizarre as a result of changes induced by hypoxia, necrosis or antifungal therapy. Although the disease cannot be named in such instances, the pathologist can nevertheless often conclude that a fungal infection is present and apply a panel of specific antibodies using different immunohistochemical techniques (Jensen et al. 1996).

The histomorphological features of the common pathogenic fungi and related microorganisms are summarized in Table 5 and illustrated in Figures 1–62 at the end of the chapter. To facilitate differential diagnosis, the diseases cited in the table are grouped according to the morphological similarities of their etiologic agents in tissue. As diseases caused by the actinomycetes and the protothecae traditionally fall within the province of medical mycology, they are included in Table 5. Fungal infections that involve the hair exclusively, e.g. black piedra and white piedra, are not included in Table 5 because histological methods are not required for their diagnosis.

Although certain inflammatory patterns in an otherwise healthy person may suggest that a fungal infection

Table 4 *Morphological features of fungi that occur as hyaline hyphae in tissue*

Feature	*Aspergillus* spp.	*Fusarium* spp.	*Scedosporium* spp.; *Pseudallescheria boydii*	*Rhizopus* spp. and other zygomycetes
Width (μm)	3–6	3–8	2–5	6–25
Contours	Parallel	Parallel	Parallel	Irregular
Pattern of branching	Dichotomous	Dichotomous or right angle	Dichotomous and/or haphazard	Haphazard
Orientation of branches	Parallel or radial	Random and parallel	Random and parallel	Random
Frequency of septation	Frequent	Frequent	Frequent	Absent or infrequent
Angioinvasiveness	Yes	Yes	Yes	Yes

Table 5 *Histomorphological features of the common pathogenic fungi and related pathogens*

Etiologic agent(s)	Mycosis	Typical morphology
Pathogens that occur in tissue as yeast-like cells		
Blastomyces dermatitidis	Blastomycosis	Spherical, multinucleate, yeast-like cells, 7–15 μm diameter, with thick walls and single, broad-based buds
Cryptococcus neoformans	Cryptococcosis	Pleomorphic yeast-like cells, 2–20 μm diameter, with mucin-positive capsules and single or, rarely, multiple narrow-based buds; some strains are capsule-deficient and their capsular material may not be detected with mucin stain
Histoplasma capsulatum var. *capsulatum*	Histoplasmosis (classic, small form, histoplasmosis capsulati)	Spherical to oval, uninucleate, yeast-like cells, 2–4 μm diameter; often clustered because of growth within mononuclear phagocytes
Histoplasma capsulatum var. *duboisii*	African histoplasmosis (large form, histoplasmosis duboisii)	Spherical to oval uninucleate, yeast-like cells, 6–12 μm diameter, which have thick walls and bud by a narrow base, creating typical 'hour-glass' or 'figure-of-eight' forms
Loboa loboi	Lobomycosis	Spherical, budding, yeast-like cells, 5–12 μm diameter, that form chains of cells, each connected by a narrow tube-like isthmus; secondary budding sometimes present
Paracoccidioides brasiliensis	Paracoccidioidomycosis	Large, spherical, yeast-like cells 5–60 μm diameter, with multiple buds attached by narrow necks ('steering wheel' forms)
Penicillium marneffei	Infection due to *Penicillium marneffei* (penicilliosis marneffei)	Spherical to oval yeast-like cells, 2.5–5 μm diameter, with a single transverse septum; short hyphal forms and elongated, curved 'sausage' forms with one or more septa may be formed in necrotic and cavitary lesions
Sporothrix schenckii var. *schenckii*	Sporotrichosis	Pleomorphic, spherical to oval and, at times, 'cigar'-shaped yeast forms, 2–10 μm diameter, which produce single and, rarely, multiple buds
Sporothrix schenckii var. *luriei*	Sporotrichosis due to *S. schenckii* var. *luriei*	Hyaline, large (10–20 μm) thick-walled yeast forms together with the typical 'eyeglass' configuration of incompletely separated cells
Candida glabrata	Candidosis	Spherical to oval yeast-like cells 2–5 μm diameter
Pneumocystis carinii	Pneumocystosis	Thin-walled spherical, oval and crescentic trophozoites, 2–10 μm diameter; cysts are thick-walled, 4–6 μm diameter
Pathogens that occur in tissue as yeast-like cells and mycelial elements		
Candida albicans, *C. guilliermondii*, *C. krusei*, *C. parapsilosis*, *C. pseudotropicalis*, *C. tropicalis* and others	Candidosis	Oval, budding, yeast-like cells (blastoconidia), 2–6 μm diameter; pseudohyphae; and septate hyphae
Geotrichum candidum	Geotrichosis	Septate, infrequently branched hyphae, 3–6 μm wide; spherical yeast-like cells; and rectangular or oval arthroconidia, 4–10 μm wide, with rounded or squared ends
Trichosporon beigelii, *T. capitatum* (*Blastoschizomyces capitatus*)	Trichosporonosis	Pleomorphic yeast-like cells, 3–8 μm diameter; septate hyphae; and, rarely, arthroconidia
Pathogens that occur in tissue as large spherules		
Chrysosporium parvum var. *crescens*	Adiaspiromycosis	Large adiaconidia, 200–400 μm diameter, with thick (20–70 μm) walls; budding and endosporulation do not occur
Coccidioides immitis	Coccidioidomycosis	Spherical, thick-walled, endosporulating spherules, 20–200 μm diameter; mature spherules contain small, 2–5 μm diameter, uninucleate endospores; septate hyphae and chains of arthroconidia sometimes occur in necrotic nodules

(*Continued over*)

Table 5 *Histomorphological features of the common pathogenic fungi and related pathogens (Continued)*

Etiologic agent(s)	Mycosis	Typical morphology
Prototheca wickerhamii, *P. zopfii*	Protothecosis	Spherical, oval or polyhedral sporangia, 2–25 μm diameter, that, when mature, contain 2–20 sporangiospores
Rhinosporidium seeberi	Rhinosporidiosis	Large sporangia, 100–350 μm diameter, with thin walls (3–5 μm) that enclose numerous sporangiospores, 6–10 μm diameter
Pathogens that occur in tissue as hyaline hyphae		
Absidia corymbifera, *Basidiobolus ranarum*, *Conidiobolus coronatus*, *Mucor ramosissimus*, *Rhizomucor pusillus*, *Rhizopus arrhizus*, and others	Zygomycosis	Broad, thin-walled, aseptate or infrequently septate hyphae, 6–25 μm wide, with non-parallel contours and random branches. Sporangia sometimes formed in cavitary lesions with access to air
Aspergillus fumigatus, *A. flavus*, *A. niger*, and other *Aspergillus* spp.	Aspergillosis	Septate, dichotomously branched hyphae of uniform width (3–6 μm); conidial heads sometimes formed in cavitary lesions with access to air. Calcium oxalate crystals may be present in case of *A. niger*
Pathogenic members of the genera *Acremonium*, *Beauvaria*, *Cylindrocarpon*, *Fusarium*, *Paecilomyces*, *Phialomonium*, *Scedosporium*, *Scopulariopsis*, and others	Hyalohyphomycosis	Septate, branched, hyaline hyphae, 2–8 μm wide, which usually have regular contours and dichotomous random branches
Malassezia furfur	Pityriasis versicolor	Short, curved, and bent hyaline hyphae, 2–4 μm wide; and clusters of spherical to oval, thick-walled phialoconidia, 3–8 μm diameter
Pathogenic members of the genera *Epidermophyton*, *Microsporum*, and *Trichophyton*	Dermatophytosis	Branched, septate hyphae that break up into chains of arthroconidia
Pseudallescheria boydii (anamorph of *Scedosporium apiospermum*)	Pseudallescheriosis (scedosporidiosis)	Septate, randomly branched hyphae, 2–5 μm wide; conidia of scedosporium type may be formed in cavitary lesions
Pigmented (pheoid) nonmycetomatous pathogens		
Phaeoannellomyces werneckii, *Stenella araguata*	Tinea nigra	Pheoid, branched, septate hyphae, 1–3 μm wide; and elongated budding cells, 1–5 μm diameter
Cladophialophora carrionii, *Fonsecaea compacta*, *F. pedrosoi*, *Phialophora verrucosa*, and *Rhinocladiella aquaspersa*	Chromoblastomycosis	Large, 6–12 μm diameter, spherical to polyhedral, thick-walled, dark-brown, muriform cells (sclerotic bodies) with septations along one or two planes; pheoid hyphae sometimes present
Bipolaris spicifera, *Cladophialophora bantiana*, *Exophiala jeanselmei*, *Phialophora parasitica*, and other pheoid fungi	Pheohyphomycosis	Pheoid (brown) hyphae, 2–6 μm wide, which may be branched and are often constricted at their frequent and prominent septations; pheoid yeast forms, and chlamydoconidia sometimes present
Mycetomatous pathogens		
Acremonium spp., *Aspergillus nidulans*, *Curvularia geniculata*, *Exophiala jeanselmei*, *Leptosphaeria senegalensis*, *Madurella grisea*, *M. mycetomatis*, *Neotestudina rosatii*, *Pseudallescheria boydii*, *Pyrenochaeta romeroi*, and others	Mycetoma (eumycotic) or eumycetoma	Granules, 0.2 mm to several millimeters in diameter, composed of broad (2–6 μm), hyaline or phaeoid, septate hyphae that often branch, and form chlamydoconidia
Actinomadura madurae, *A. pelletieri*, *Nocardia* spp., *Nocardiopsis dassonvillei*, *Streptomyces somaliensis*, and others	Mycetoma (actinomycotic) or actinomycetoma	Granules, 0.1 mm to several millimeters diameter, composed of delicate gram-positive filaments, 1 μm wide, which are often branched, and beaded
Filamentous bacterial pathogens		
Actinomyces israelii, *A. meyeri*, *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, *Arachnia propionica*, *Rothia dentocariosa*, and others	Actinomycosis	Organized aggregates (granules) composed of delicate, branched, gram-positive filaments, 1 μm wide, that are often beaded; entire granules are 30–3000 μm diameter
Nocardia asteroides, *N. brasiliensis*, and *N. otitidiscaviarum*	Nocardiosis	Delicate, branched, individual filaments, 1 μm wide, that are gram-positive, weakly acid-fast, and often beaded

exists, there are no absolute histological criteria that permit an etiologic diagnosis based only on host response. In addition, inflammatory patterns are often atypical and unreliable in immunodeficient patients. A fungus must first be detected and then identified in tissue sections before a definitive histopathological diagnosis can be made. Knowledge of the patient's travel history may help resolve differential diagnostic problems because the geographic distribution of some pathogenic fungi is limited (Warnock et al. 1998).

DIAGNOSTIC APPLICATION OF IMMUNOHISTOCHEMICAL TECHNIQUES

The prerequisite for all immunohistochemical staining systems is a primary antibody properly characterized especially in terms of specificity under optimal conditions (Jensen 1994). The technique used for obtaining an immunohistochemical diagnosis of mycoses may be either direct (conjugated primary antibodies) or indirect (conjugated secondary antibodies or tertiary enzyme complexes). In accordance with other immunohistochemical staining systems, the reaction complexes may be vizualized with the help of fluorochromes [e.g. fluorescein isothiocyanate (FITC) and tetra-methylrhodamine isothiocyanate isomer R (TRITC)], gold-silver complexes, or complexes of enzymes [e.g. peroxidase–antiperoxidase (PAP) techniques, and alkaline phosphatase-antialkaline phosphatase (APAAP) techniques] (El Nageeb and Hay 1981; Kaufman 1992; Jensen 1994). Also, avidin–biotin enzyme complex (ABC) methods may be used with horseradish peroxidase (HRP) and galactosidase (Jensen et al. 1996). The major advantage of using enzyme immunohistochemistry compared with immunofluorescence techniques is that permanent sections are provided, specialized microscopic equipment is not needed, and pathological reactions may be assessed simultaneously during the evaluation of the immunoreactivity (Jensen 1994; Jensen et al. 1996). Application of immunohistochemical techniques may, in several cases, be the only means of establishing an accurate etiologic diagnosis in fixed tissue sections because of morphological similarities among the tissue forms of several fungal genera (e.g. aspergillosis, fusariosis, and scedosporiosis), when atypical forms of a fungus are present, or when fungal elements are sparse (Jensen et al. 1996). A range of different forms of fungal elements are frequently observed within lesions, especially when more than one organ is studied, and it must be ascertained whether these elements belong to a single or more taxa. In such cases, dual immunostaining techniques are useful tools for obtaining a reliable diagnosis (Jensen et al. 1996). In the case of *Cryptococcus neoformans*, the combination of reactions obtained by different primary antibodies is used to differentiate between serotypes (Krockenberger et al. 2001)

Apart from tissue sections, immunohistochemical techniques can also be used to identify fungi in smears of lesional exudates, bronchial washings, bronchoalveolar lavage fluid, blood, bone marrow, cerebrospinal fluid, and in sputum specimens that have been enzymatically or chemically digested.

An important limitation to the widespread application of immunohistochemical techniques and their use in the routine diagnosis of mycoses lies in the fact that sensitive and specific reagents are usually derived from multiple heterologously adsorbed polyclonal antisera, which are not commercially available (Jensen et al. 1996). However, in recent years more specific monoclonal antibodies have been developed, some of which can be obtained through companies offering diagnostic reagents (Jensen et al. 1997). Moreover, in addition the development of specific DNA probes for in situ hybridization techniques may facilitate the access to specific fungal identification (Jensen et al. 1996). In Table 6, fungi and related pathogens, which can be identified immunohistochemically, are listed.

Before immunostaining, localization and presumptive identification of fungal elements in GMS-stained tissue sections enable the pathologist to narrow the etiologic

Table 6 *Fungal and related pathogens that can be identified immunohistochemically in deparaffinized sections of formalin-fixed tissue*

Fungal and related pathogens
Actinomycetes
Actinomyces israelii
Actinomyces naeslundii
Actinomyces viscosus
Arachnia propionica
Fungi
Aspergillus to the genus level or to the species level, i.e. *A.fumigatus*, *A. flavus*, and *A. niger*
Blastomyces dermatitidis
Candida to the genus level or to the species level, i.e. *C. albicans*, *C. glabrata*, *C. tropicalis*
Coccidioides immitis
Cryptococcus neoformans to the genus level or to the level of varieties and serotypes, i.e. *C. neoformans* var. *neoformans* (A, D, and AD) and *C. neoformans* var. *gatti* (B and C), respectively
Fusarium spp.
Geotrichum candidum
Histoplasma capsulatum (tissue forms of capsulatum and duboisii varieties)
Paracoccidioides brasiliensis
Penicillium marneffei
Pneumocystis carinii
Pseudallescheria boydii and *Scedosporium* spp.
Sporothrix schenckii var. *schenckii*
Trichosporon beigelii and *Trichosporon capitatum* (*Blastoschizomyces capitatus*)
Zygomycotic fungi (Order Mucorales) to the level of genus, i.e. *Absidia*, *Rhizopus*, and *Rhizomucor*
Algae
Prototheca wickerhamii
Prototheca zopfii

Table 7 *Special terminology*

Term	Definition
Anamorph	A somatic or reproductive structure of the asexual cycle
Adiaconidium	Asexual conidium (spore) that enlarges after formation in vitro or implantation in vivo; adiaconidia do not reproduce in vivo
Arthroconidium	Asexual conidium (spore) formed by mycelial disarticulation
Asteroid body	Radially oriented Splendore–Hoeppli material that sometimes surrounds the yeast-like cells of *Sporothrix schenckii* or other fungi in tissue
Bud (blastoconidium)	Variety of conidium produced by lateral outgrowth from a parent cell; buds may be single or multiple
Budding	Asexual reproductive process characteristic of unicellular fungi or conidia in which a lateral outgrowth from the parent cell is pinched off to form a new cell
Capsule	Hyaline (colorless) mucopolysaccharide coat external to the wall of a fungal cell or conidium
Chlamydoconidium	Thick-walled, rounded, resistant conidium formed by direct differentiation of the mycelium
Coenocytic	Nonseptate
Conidiophore	Specialized hypha that produces and bears conidia
Conidium (plural, conidia)	Asexual propagule formed on, but easily detached from, a hypha, conidiophore, or other parent cell
Dematiaceous	Naturally pigmented, usually brown or black; term considered to be obsolete; replacement by the term pheoid advocated
Dichotomous	Equal branching of hyphae
Dimorphic	Having two forms; growth as hyphae in vitro at 25°C and as budding yeasts, muriform cells, or spherules in infected tissues or in vitro at 37°C on special media
Endospore	Asexual spore formed within a closed structure such as a spherule
Endosporulation	Process of producing endospores
'Fruiting body'	Imprecise term for conidia-bearing organs produced by fungi
Germ tube	Tube-like process, produced by a germinating conidium, which eventually develops into a hypha
Granule (grain)	Mass of organized mycelium that may be embedded in a cement-like matrix; formed in actinomycosis and in mycetomas caused by fungi and aerobic actinomycetes
Hyaline	Colorless
Hypha (plural, hyphae)	Filament that forms the thallus or body of most fungi
Intercalary	Between two fungal cells
Muriform	Having horizontal and vertical septations or cross-walls
Mycelium (pl. mycelia)	Mass of intertwined and branched hyphae
Perfect state	Developmental state of a fungus when sexual reproduction takes place and sexual spores are produced
Pheoid	Dark, dusky; term applied to fungal cell walls darkened by melanins
Phialide	A conidiogenous cell that successively produces and extrudes conidia from within
Pseudohypha	Short hyphal-like filament produced by successive yeast buds that elongate and fail to separate
Schizogony	Process of multiplication of yeasts by the splitting and separation of a septum that permits adjacent cells to be set free
Septate	Having cross-walls
Septum (pl. septa)	Cross-wall of a mycelial filament or conidium
Spherule	Closed, thick-walled, spherical structure within which asexual endospores are produced by progressive cytoplasmic cleavage
Splendore–Hoeppli material	Eosinophilic, refractile, homogeneous and often radially oriented material sometimes found around fungi in tissue sections; represents a localized antigen–antibody reaction in a hypersensitized host
Sporangium (pl. sporangia)	A closed structure within which asexual spores (sporangiospores) are produced by cytoplasmic cleavage
Sterigma (pl. sterigmata)	Short or elongate specialized projection of a conidiophore on which conidia are developed (see Phialide)
Yeast	Spherical to oval unicellular fungus that reproduces by a budding or fission process

possibilities, so that the most appropriate panel of immunoreagents can be employed. Depending on the nature of reactive fungal epitopes, pretreatment with enzymes (e.g. trypsin and pepsin) and addition of a substance such as dimethyl sulfoxide may enhance the reactivity of tests on formalin-fixed tissues. A number of appropriate control procedures are essential in the evaluation of immunohistochemical diagnostic assays, e.g. replacement of antifungal antibodies by antibodies raised against irrelevant antigens and including both positive and negative control sections with each batch of slides (Jensen et al. 1996).

As the somatic and cell wall antigens of most pathogenic fungi survive formalin fixation and processing into paraffin quite well, immunohistochemical and in situ techniques can be performed retrospectively on archival material. Unstained sections, paraffin blocks, or formalin-fixed 'wet' tissue can be sent to specialized reference centers for immunohistopathology. If the number of sections available is limited, those already stained with H&E, Giesma or tissue Gram's stains can be decolorized in acid–alcohol and reused for immunohistochemistry. If immunofluorescence is used, as much as possible of the eosin should be removed because this stain autofluoresces. In cases where the antigenic epitope is a polysaccharide, sections previously stained with GMS, PAS, or GF procedures are not suitable for immunohistochemistry, because oxidation of the cell wall polysaccharides irreparably alters the antigenicity of the fungal cells.

SPECIAL TERMINOLOGY

As medical mycology and the histopathology of mycotic diseases are highly specialized disciplines, the following selected terms, used to describe the appearance of fungi and related pathogens in tissue sections, are defined as shown in Table 7.

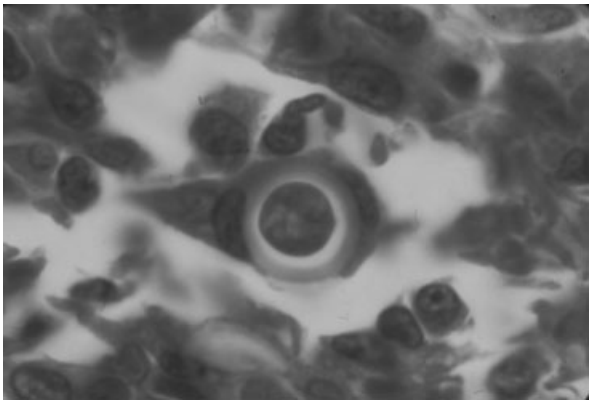

Figure 1 *Pulmonary blastomycosis: a multinucleated giant cell contains a single yeast form of* Blastomyces dermatitidis. *In tissue, the cells of this fungus are yeast-like, spherical to oval, 8–15 μm in diameter, and have thick 'doubly contoured' walls and single buds attached to parent cells by a broad base. Note that the fungal cell is multinucleate. H&E; magnification × 1 125*

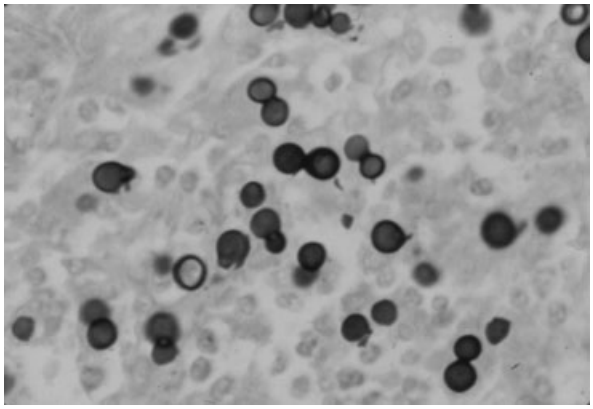

Figure 2 *Pulmonary blastomycosis in an immunocompromised patient. Numerous yeast-like cells of* Blastomyces dermatitidis *fill alveolar spaces. Note the diagnostic broad-based budding, thick cell walls, and variation in size of fungal cells. GMS; magnification × 360*

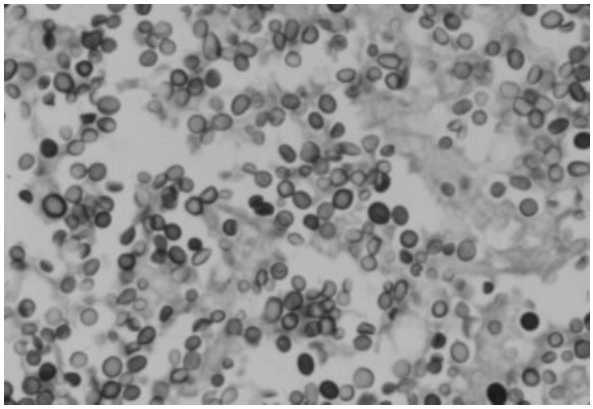

Figure 3 *Disseminated cryptococcosis: pleomorphic yeast forms of* Cryptococcus neoformans *are predominantly extracellular, bud by a relatively narrow base, range from 2 to 20 μm in diameter, and are surrounded by unstained (optically clear) capsules. A multiple-budding cell is seen at left center. GMS; magnification × 225*

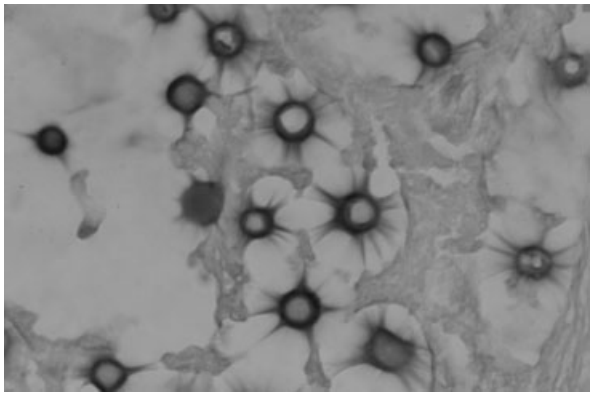

Figure 4 *Cerebromeningeal cryptococcosis: yeast-like cells of* Cryptococcus neoformans *distend the leptomeninges, elicit little or no inflammation, and are surrounded by wide, carminophilic capsules that have a crenated or spinous appearance because of uneven shrinkage during tissue processing. Mayer's mucicarmine; magnification × 563*

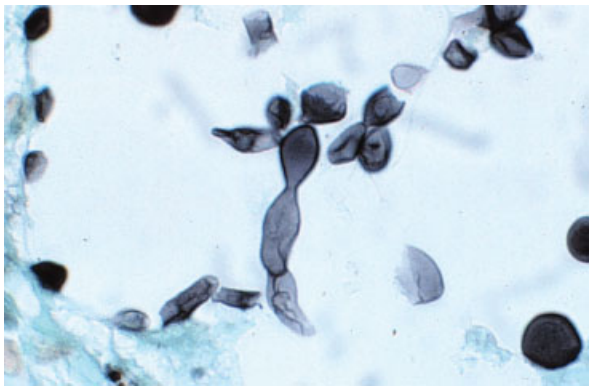

Figure 5 *Hepatic cryptococcosis: the cells of* Cryptococcus neoformans *may sometimes form hyphae and pseudohyphae that may be confused with elements of candidosis. GMS; magnification* × *360*

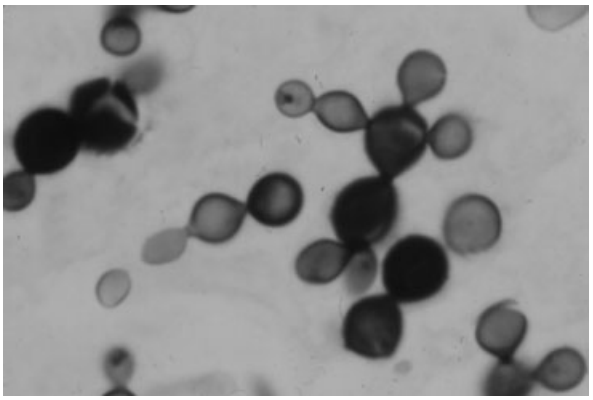

Figure 8 *Lobomycosis: spherical to oval and budding yeast-like cells of* Loboa loboi, *5–12 μm in diameter, are attached in chains. Budding cells are often connected by a narrow, tube-like isthmus. GMS; magnification* × *1 125*

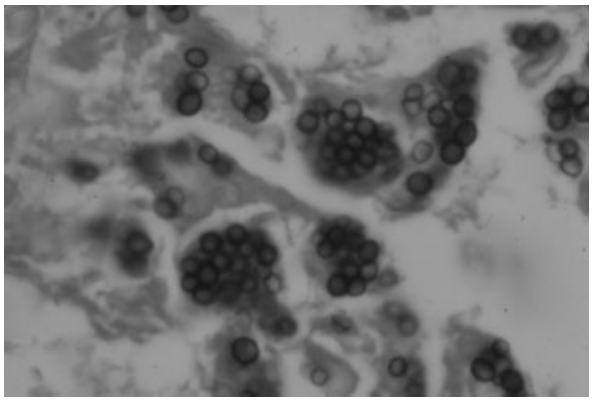

Figure 6 *Disseminated histoplasmosis involving the adrenal gland. Numerous spherical to oval yeast forms of* Histoplasma capsulatum *var.* capsulatum, *2–4 μm in diameter, have single buds attached to parent cells by a relatively narrow base, and are clustered within histiocytes. GMS; magnification* × *1 125*

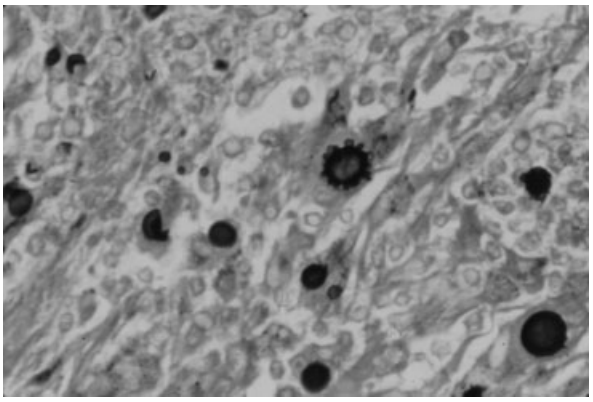

Figure 9 *Pulmonary paracoccidioidomycosis. A granuloma contains diagnostic, multiple-budding ('steering wheel') yeast forms of* Paracoccidioides brasiliensis *(right center), as well as nonbudding and single-budding cells that range from 10 to 60 μm in diameter. Note the small detached blastoconidia. GMS; magnification* × *225*

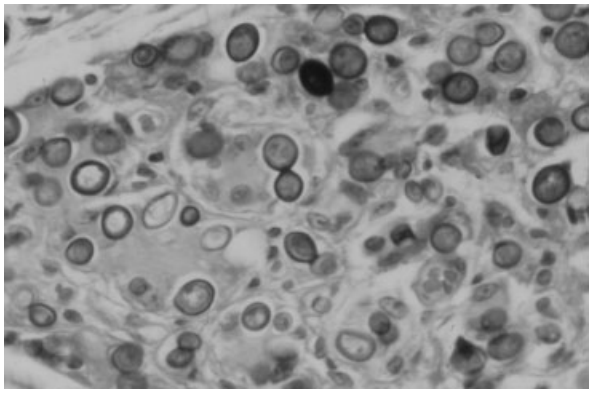

Figure 7 *Cutaneous lesion of African histoplasmosis. Histiocytes and multinucleated giant cells contain numerous yeast-like cells of* Histoplasma capsulatum *var.* duboisii, *8–15 μm in diameter. Note the classic 'double-cell' yeast form (top center) with narrow-based bud and thick cell walls. GMS–H&E; magnification* × *360*

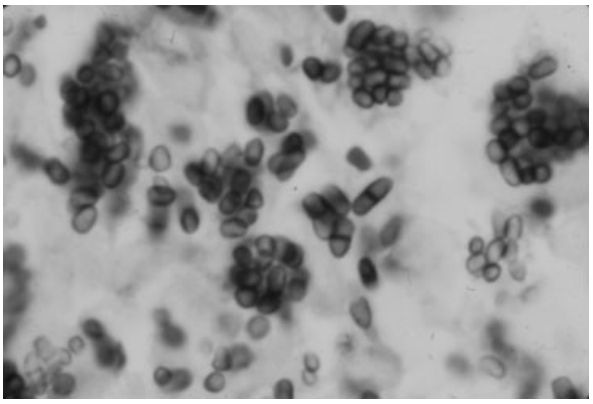

Figure 10 *Disseminated* Penicillium marneffei*: hepatic granuloma contains individual and clustered, spherical to oval yeast-like cells of* Penicillium marneffei, *2.5–5.0 μm in maximum diameter. Note the diagnostic yeast forms with single, wide, transverse septa. GMS; magnification* × *1 125*

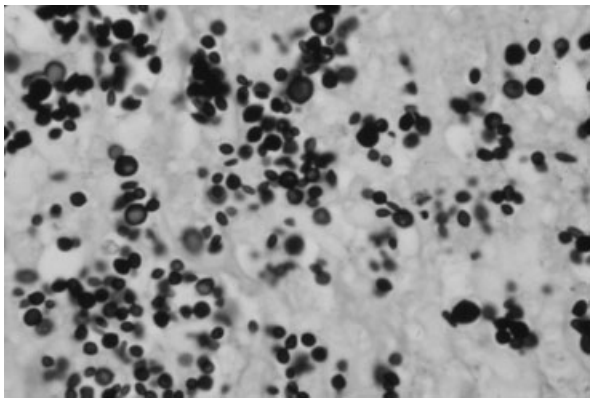

Figure 11 *Disseminated sporotrichosis: pleomorphic spherical and elongated (cigar-shaped) yeast-like cells of* Sporothrix schenckii *are located in a testicular granuloma. GMS; magnification* × *1 125*

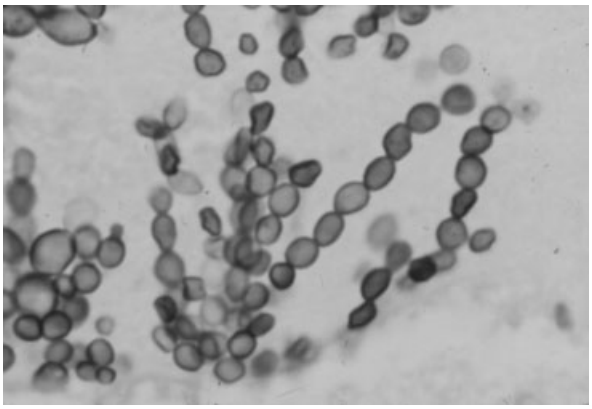

Figure 14 *Disseminated candidosis: numerous yeast-like cells and mycelial elements of* Candida albicans *occupy a nodular infarct in the lung of a granulocytopenic patient. GMS; magnification* × *563*

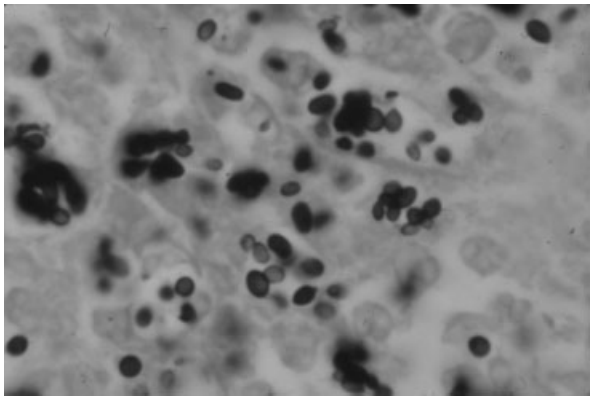

Figure 12 *Disseminated candidosis. Individual and clustered yeast-like cells of* Candida glabrata *are spherical to oval, 2–5 μm in diameter, have single buds attached to parent cells by a relatively narrow base, and resemble those of* Histoplasma capsulatum *var.* capsulatum. *GMS; magnification* × *1 125*

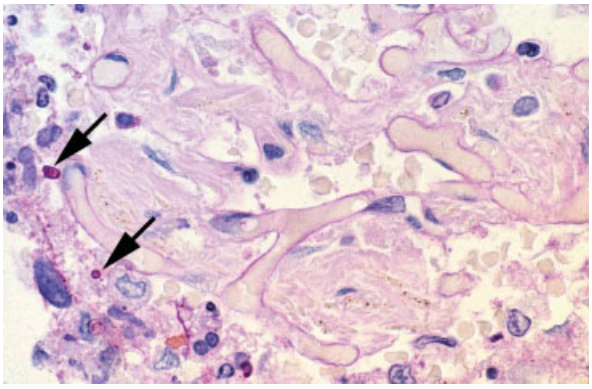

Figure 15 *Pulmonary candidosis: capillaries may sometimes be mistaken for fungal hyphae. However, by paying special attention, endothelial cells usually can be identified. In the present case, only a few PAS-positive* Candida glabrata *cells were demonstrated (arrows). PAS; magnification* × *360*

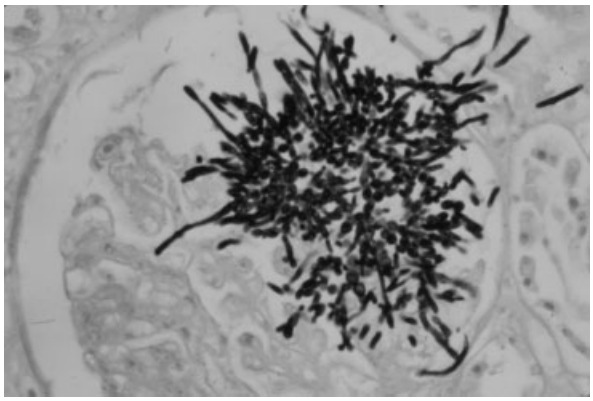

Figure 13 *Renal candidosis caused by* Candida albicans. *Blastoconidia (budding yeast-like cells), pseudohyphae and true hyphae proliferate in a radial pattern, and efface the normal renal architecture. GMS; magnification* × *225*

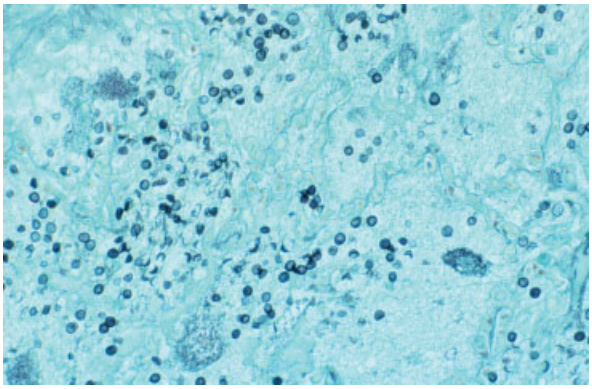

Figure 16 *Pulmonary pneumocystosis.* Pneumocystis carinii – *'cysts' and 'trophozoites' are seen as round, distorted, or crescent structures from 3 to 8 μm in diameter. GMS; magnification* × *360*

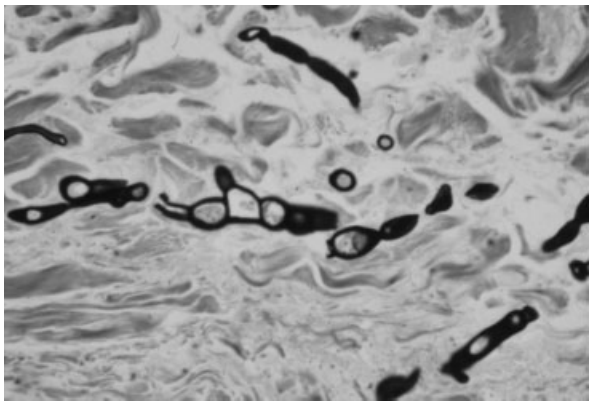

Figure 17 *Cutaneous geotrichosis: individual hyphae of* Geotrichum candidum *have non-parallel contours and prominent septa, and branch at acute angles. Spherical yeast-like cells and rectangular arthroconidia, 4–10 μm wide, with rounded or squared ends are also produced by this fungus. GMS; magnification × 360*

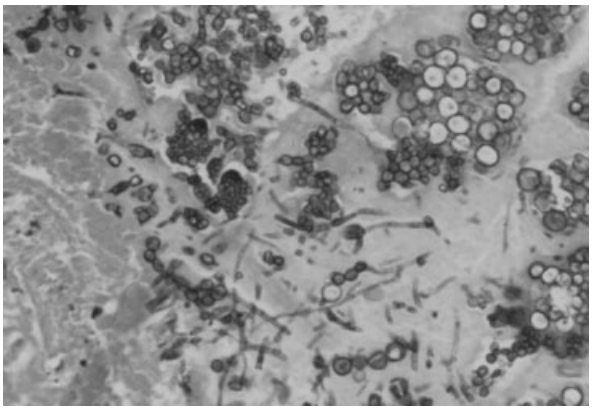

Figure 20 *Miliary pulmonary coccidioidomycosis: necrotic nodule contains characteristic endosporulating spherules, immature spherules, hyphae and arthroconidia (lower centre) of* Coccidioides immitis. *GMS–H&E; magnification × 113*

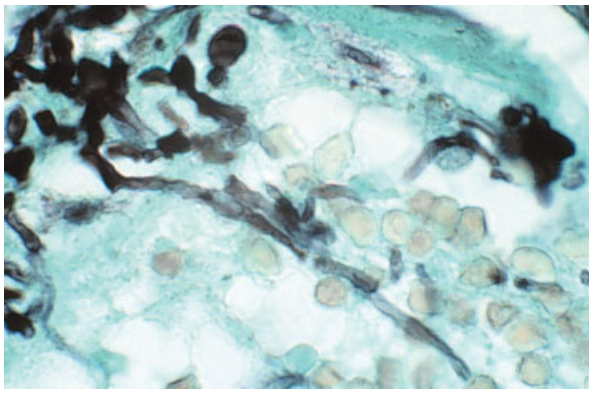

Figure 18 *Disseminated trichosporonosis: a splenic infarct contains radiating, septate hyphae and pleomorphic yeast-like cells of* Trichosporon beigelii. *GMS; magnification × 360*

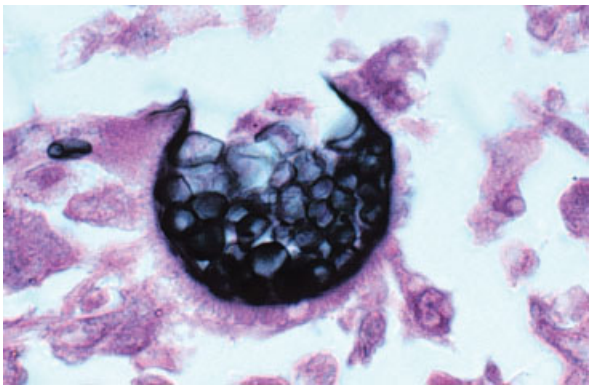

Figure 21 *Coccidioidomycosis: an intact endosporulating spherule of* Coccidioides immitis *is located in a pulmonary granuloma. GMS–H&E; magnification × 563*

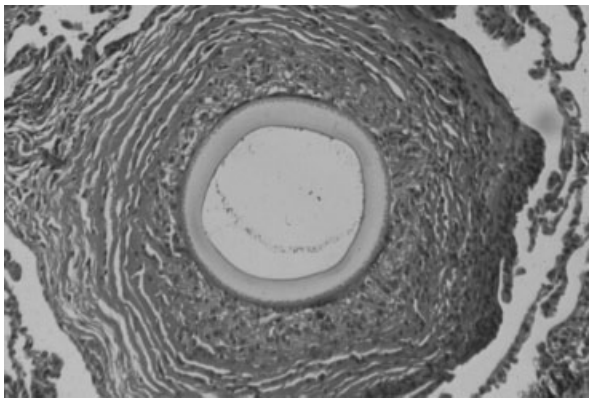

Figure 19 *Adiaspiromycosis: a large, spherical, thick-walled adiaconidium of* Chrysosporium parvum *var.* crescens *is surrounded by a fibrogranulomatous reaction in a lung biopsy specimen. The interior of the conidium is empty. Budding and endosporulation do not occur. H&E; magnification × 56*

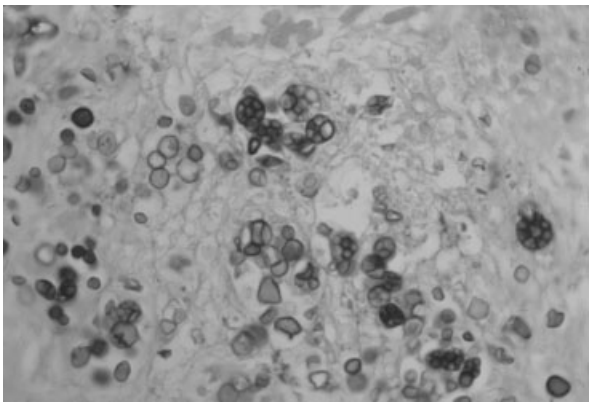

Figure 22 *Prototheca l olecranon bursitis: a necrotizing granuloma contains numerous single and endosporulating sporangia of* Prototheca wickerhamii. *Note the characteristic 'morula' forms. Gridley; magnification × 225*

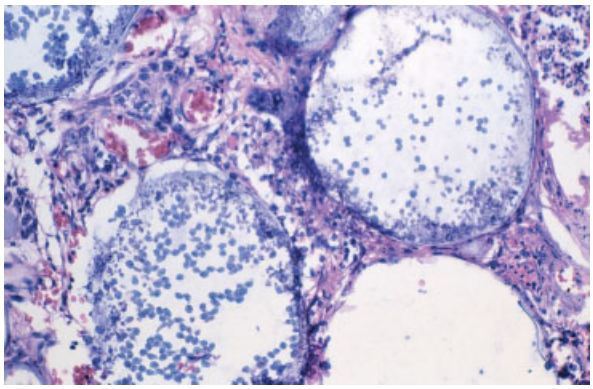

Figure 23 *Rhinosporidiosis: two mature sporangia of* Rhinosporidium seeberi *with thin walls are located in the inflamed stroma of a nasal polyp. Note typical maturation and zonation of sporangiospores. H&E; magnification × 113*

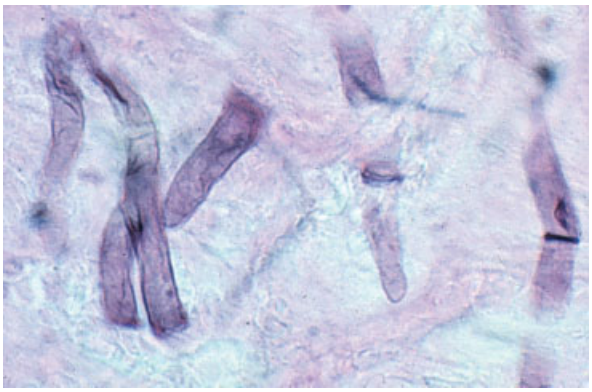

Figure 26 *Disseminated zygomycosis involving the myocardium. When hyphae with uniform wide, parallel walls, and dichotomous branching are formed, the identification may be confused with aspergillosis. PAS; magnification × 563*

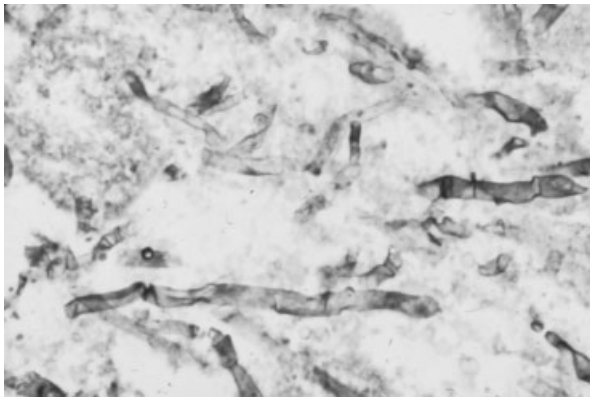

Figure 24 *Disseminated zygomycosis involving the myocardium. Typical hyphae of the mucoraceous zygomycetes are 6–25 μm wide, thin walled, infrequently septate, and have nonparallel contours and random branches. Hyphae of the zygomycetes are weakly stained with GMS procedure. GMS; magnification × 360*

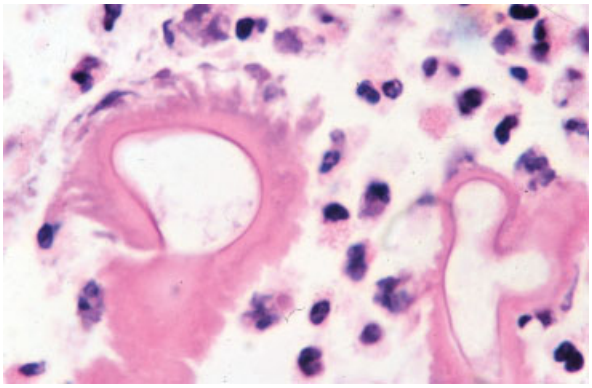

Figure 27 *Zygomycotic enteritis. Around hyphae, huge amounts of eosinophilic, homogenous and radially radiating Splendore-Hoeppli material has formed. H&E; magnification × 1 125*

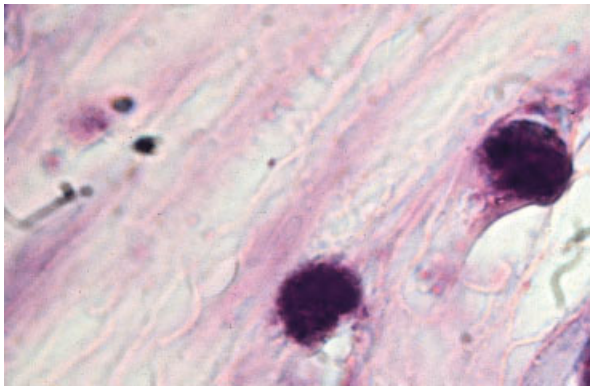

Figure 25 *Pulmonary zygomycosis caused by* Absidia corymbifera. *In tissues with access to air, sporangia are sometimes produced. If sectioned optimally, the sporangia may be useful for the identification of the fungus. H&E; magnification × 360*

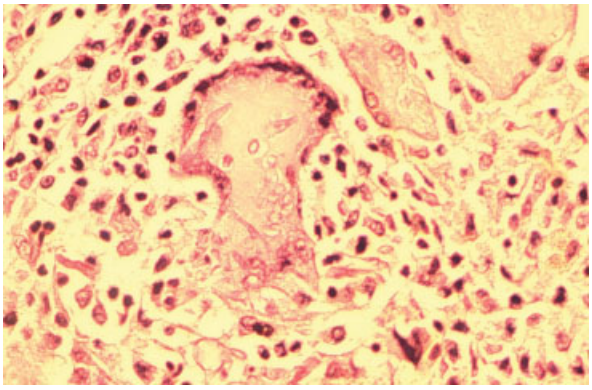

Figure 28 *Chronic zygomycotic lymphadenitis. Within the giant cells only sparse fungal elements are seen. The identification of elements as belonging to the zygomycetes was confirmed by immunohistochemistry. (Compare with Figure 59.) H&E; magnification × 360*

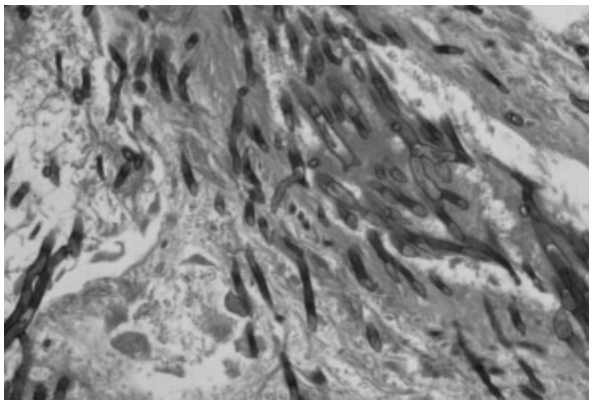

Figure 29 *Invasive pulmonary aspergillosis: hyphae of the Aspergillus spp. are septate, uniform in width (3–6 μm), have parallel contours, and branch progressively and dichotomously. The aspergilli are readily demonstrated with GMS and other special histological stains for fungi. GMS; magnification × 360*

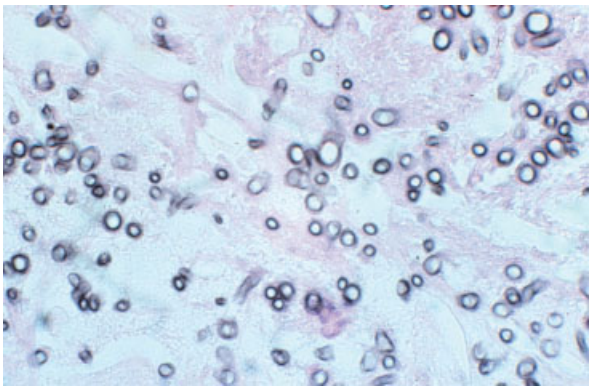

Figure 32 *Pulmonary aspergillosis. In cross-section, hyphae of* Aspergillus *spp. may be confused with yeast cells. However, the elements may easily be identified as* Aspergillus *spp. by immunohistochemistry. (Compare with Figure 55.) GMS; magnification × 563*

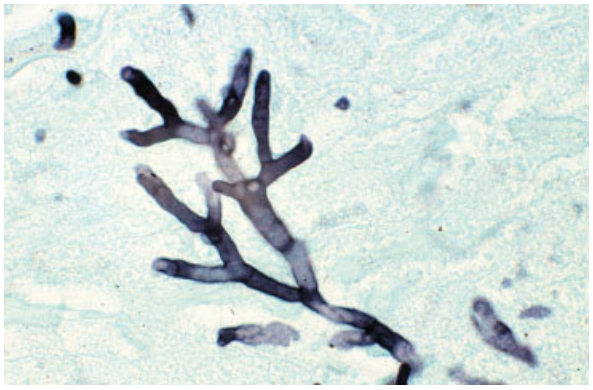

Figure 30 *Disseminated aspergillosis involving the myocardium. The hyphae present are typical of* Aspergillus *spp. They are frequently septate, have uniform widths (3-6 μm), have parallel contours, and branch dichotomously. GMS; magnification × 563*

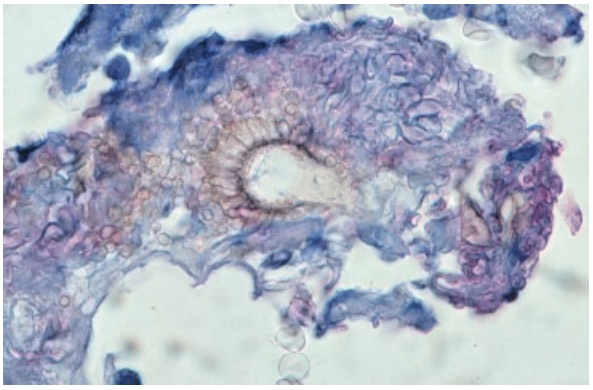

Figure 33 *Pulmonary aspergillosis caused by* Aspergillus fumigatus. *In tissues with access to air, conidial heads are sometimes produced. If the conidial heads are cut optimally they are useful for the identification of the fungus. H&E; magnification × 563*

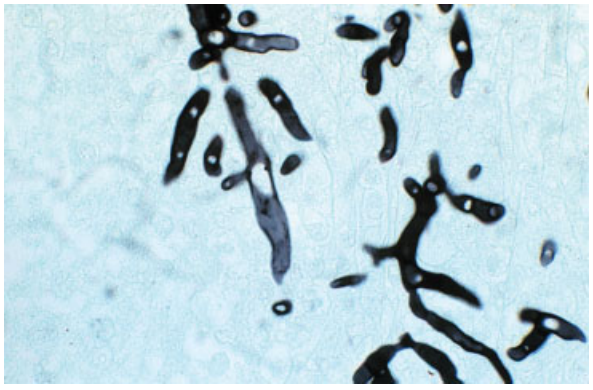

Figure 31 *Cerebral aspergillosis caused by* Aspergillus fumigatus. *Hyphae of* Aspergillus *spp. may adapt to highly bizarre forms in chronic lesions, which may be confused with hyphae of zygomycotic fungi. GMS; magnification × 360*

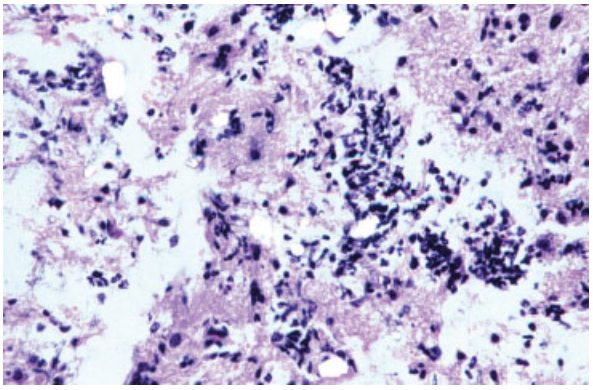

Figure 34 *Cerebral aspergillosis caused by* Aspergillus niger. *Deposits of birefringent calcium oxalate crystals are sometimes observed in lesions caused by* Aspergillus niger. *H&E and polarized light; magnification × 225*

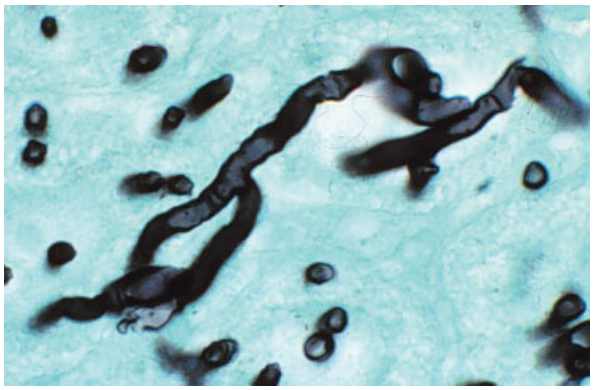

Figure 35 *Renal fusariosis caused by* Fusarium solani. *Hyphae in cross-sections and longitudinal sections are seen. Hyphae are septate, 3–8 μm wide and branch at dichotomous angles. Often fusariosis cannot be differentiated from aspergillosis and scedosporiosis. GMS; magnification × 563*

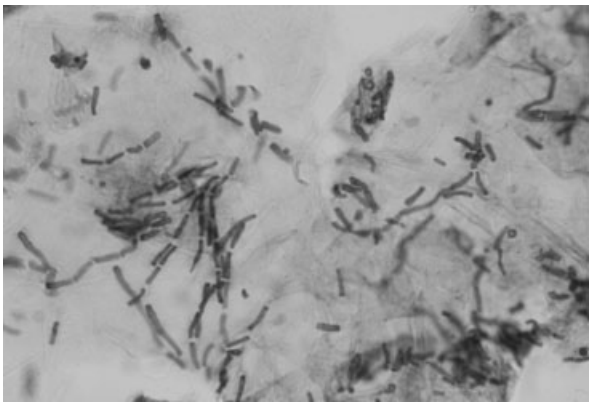

Figure 38 *Pityriasis versicolor: in skin scrapings,* Malassezia spp. *appear as clusters of single and budding yeast-like cells, 3–8 μm in diameter, mixed with short, narrow and sometimes curved hyphal fragments, 2.5–4 μm wide, that are oriented end to end. PAS; magnification × 225*

Figure 36 *Cerebral scedosporiosis caused by* Scedosporium apiospermum. *Hyphae of* Scedosporium *spp. are septate, 3–8 μm wide and branch at dichotomous angles. Often scedosporiosis cannot be differentiated from aspergillosis and fusariosis. GMS; magnification × 563*

Antifungal agents and antifungal susceptibility testing

SANJAY G. REVANKAR, JOHN R. GRAYBILL, AND THOMAS F. PATTERSON

Systemic antifungal drugs in current use	2	Methods of susceptibility testing	11
Future antifungal drugs	9	References	12
Antifungal susceptibility testing	9		

In the late nineteenth century, the appreciation of systemic infections by *Coccidioides immitis* and *Histoplasma capsulatum* launched an effort to find effective treatment for these rare, debilitating, and lethal diseases. Unfortunately, broad-spectrum agents were not discovered until the 1950s, in the forms of amphotericin B, hamycin, filipin, and nystatin. As a result of their great toxicity, only hamycin and nystatin survived as topical drugs, and amphotericin B as a systemic drug. As fungal infections were rather esoteric, relatively few physicians used amphotericin B. In more recent decades, the increasing use of antibacterial drugs, immunosuppressive agents, and prosthetic implanted devices, and the appearance of the acquired immunodeficiency syndrome (AIDS) provided settings for a dramatic increase in fungal infections, and a subsequent increase in the development of systemic antifungal drugs.

Flucytosine was introduced in the 1960s. Although rapidly active as an antimetabolite, the spectrum was limited to *Candida* spp. and *Cryptococcus neoformans*, and the drug now is used only in combination with amphotericin B (Francis and Walsh 1992).

A new era in antifungal therapy was introduced with the azole antifungals, developed with the aim of reducing toxicity and improving efficacy against fungal pathogens. The first of these drugs was clotrimazole. When given parenterally, clotrimazole was soon found to activate the hepatic cytochrome enzymes responsible for its degradation, a sort of suicide effect, which limited its use as a systemic antifungal agent. Presently, clotrimazole is used only for topical therapy of mucosal candidiasis and for dermatophyte infections. The second of the imidazole drugs was miconazole, which was used intravenously for several years. Unfortunately, the carrier vehicle caused severe histamine-mediated reactions, and miconazole today is used almost exclusively topically (Stevens 1977; Heel et al. 1980).

The major breakthrough in antifungal drug development was ketoconazole, which was released in the late 1970s. Ketoconazole has a broad antifungal spectrum, is absorbed when given orally, and is much better tolerated than amphotericin B or flucytosine (Dismukes et al. 1983; Saag et al. 1985; Sugar et al. 1987; Graybill 1989, 1990; Bodey 1992; Como and Dismukes 1994). However, its lack of oral absorption in seriously ill patients, its poor central nervous system penetration, and its lack of activity against molds limited its clinical use. Thus, in the late 1980s, ketoconazole was supplemented and, in some countries supplanted by, the more recently developed azoles fluconazole and itraconazole (Como and Dismukes 1994). These triazole antifungals are very well tolerated and achieve significant activity in systemic disease. Modifications of these molecules are aimed at further improvement of their clinical properties.

During this period of azole expansion, multiple efforts to modify the amphotericin B molecule to improve tolerance were initiated, but they all failed because of toxicity. The most recent efforts involved incorporating amphotericin B or other toxic antifungals such as nystatin into lipid vehicles, which reduce the dose-limiting toxicity of those compounds. Despite continuing advances, none of the drugs presently available is

absolutely fungicidal, either in vivo or in vitro, so that further advances in antifungal drugs are still needed.

SYSTEMIC ANTIFUNGAL DRUGS IN CURRENT USE

Polyenes

MECHANISM OF ACTION

The polyenes are macrolide antibiotics with unsaturated diene bonds. All the polyenes rapidly bind to sterols, preferentially to ergosterol, the primary fungal cell membrane sterol, and less avidly to cholesterol, the primary mammalian cell membrane sterol (Table 1). The consequences of this binding include disruption of osmotic integrity of the membrane, with leakage of intracellular potassium and magnesium (Hamilton-Miller 1974; Hammond 1977; Kuroda et al. 1978; Brajtburg et al. 1980, 1986; Vertut-Doi et al. 1994; Wasan et al. 1994). The polyenes also disrupt the function of oxidative enzymes in target cells (Wilson et al. 1991). Of the polyenes in use, amphotericin B is the only one with a toxicity that is sufficiently limited to permit intravenous administration. However, tolerance is also limited by toxic effects on renal cells, with secondary renal tubular acidosis and hypokalemia. Ultimately there is glomerular failure, suppression of erythropoietin synthesis, and anemia (MacGregor et al. 1978). Other systemic symptoms include chills, fever, and nausea. The spectrum of antifungal activity of polyenes is similar and broad; few fungal species are resistant to these compounds. Resistance is most commonly mediated by substitution of ergosterol by other sterols in fungal cell membranes (Woods et al. 1974). Resistance tends to be species dependent and emerges uncommonly and slowly in isolates from patients treated with amphotericin B (Woods et al. 1974; Pappagianis et al. 1979; Dick et al. 1980; Guého et al. 1994; Matsumoto et al. 1994). These include *Candida lusitaniae*, *Fusarium* spp., *Trichosporon beigellii*, *Pseudallescheria boydii*, and *Scedosporium prolificans*. Some other species of *Candida* may develop lesser degrees of resistance.

Despite the very broad range of amphotericin B susceptibility, there has been a study suggesting that higher minimum inhibitory concentration (MIC) of *Candida* species are correlated with clinical failure (Vanden Bossche et al. 1994b). Nguyen et al. (1998) have reviewed in vitro responses and outcome in 105 patients treated with amphotericin B. They found that isolates with an MIC at 24 hours $\geqslant$1 μg/ml correlated with more clinical failures than those with MIC $<$1 μg/ml. They also found that the minimum lethal concentration (MLC) was even more useful, correlating well with failure ($P<0.03$). In their study an MLC $>$1 μg/ml was associated with 78 percent failure in 18 patients, versus only 22 percent failures in 87 patients with isolates having MLC $\leqslant$1 μg/ml. Their method utilized antibiotic medium 3, which is now recommended for amphotericin B testing.

NYSTATIN

This drug is used topically, as an oral suspension at a concentration of 100 000 units/ml for mucosal candidiasis, where it is marginally effective. It is also used in ophthalmic preparations and other ointments.

AMPHOTERICIN B

The most widely used form of amphotericin B is commercially available as a deoxycholate and is infused

Table 1 *Antifungal mechanisms of action*

Target	Chemical class	Antifungal agent
DNA/RNA synthesis	Pyrimidine	Flucytosine
Membrane barrier function	Polyenes	Amphotericin B, nystatin
Ergosterol synthesis		
Squalene epoxidase	Allylamines	Terbinafine, naftifine
14α-Demethylase	Azoles	
	Imidazoles	Clotrimazole, econazole, ketoconazole, miconazole
	Triazoles	Fluconazole, itraconazole, voriconazole, posaconazole
Δ^{14}-Reductase/Δ^{7}–Δ^{8}-isomerase	Morpholines	Amorolfine
Mitosis (sliding of microtubules)		Griseofulvin
1,3-β-Glucan synthesis	Echinocandins	Caspofungin, anidulafungin, micafungin
Metabolite uptake	Pyridone	Ciclopiroxolamine
Chitin synthase	Nikkomycin	Nikkomycins K, Z, T
Cell wall	Pradimicin	BMS-181184
Protein synthesis (elongation factor 2)	Sordarins	GM-237354

Adapted from Vanden Bossche et al. (1994a).

intravenously at doses ranging from 0.3 to 1.5 mg/kg over 1–4 hours (Gallis et al. 1990). The optimal time of infusion has been controversial. Two studies have addressed this, with conflicting conclusions. Oldfield et al. (1990) examined 128 infusions in 12 patients. They were randomized to 1 versus 4 h. Fever, rigors, and need for meperidine (pethidine) were similar in both groups, though the onset of infusion-related toxicity occurred more quickly in 1-hour infusion recipients. Conversely, Ellis et al. (1992) found that chills, meperidine dose, and maximum 7-day total pulse rise were all worse in patients receiving 1-hour infusions. Infusion-related intolerance includes fever, chills, rigors, and thrombophlebitis, which may occur in more than 70 percent of patients; hypotension occurs rarely. These side effects may be blocked by premedication with antihistamines, corticosteroids, and acetaminophen (paracetamol) (Goodwin et al. 1995). However, the efficacy of these measures remains controversial (Goodwin et al. 1995). Nephrotoxicity is dose limiting for patients who have received in excess of 5–10 g. To minimize nephrotoxicity, 1 liter of physiological saline is usually infused before amphotericin B is given (Heidemann et al. 1983). Dosing is often interrupted if serum creatinine rises above 2.5 mg/dl. Potassium wasting occurs initially as kidney tubule function is disrupted. Hypokalemia is a common toxicity of amphotericin B administration, which occurs before the development of renal insufficiency. As glomerular function later declines, patients develop typical metabolic acidosis of uremia, with potassium retention. Rapid administration to these patients may cause leaking of potassium into the plasma and, with poor clearance from the kidneys, acute hyperkalemia may develop. Although amphotericin B is highly nephrotoxic, only 10–20 percent of the dose is excreted by the kidneys. Therefore, anephric patients may receive identical doses to individuals with normal renal function.

LIPID VEHICLES FOR POLYENES

Three licensed lipid preparations are available to encase amphotericin B in lipid vehicles that bypass the kidneys, the primary site of nephrotoxicity, but permit access to phagocytic cells (Table 2). Nephrotoxicity is markedly reduced with each of these lipid preparations, but patients still encounter infusion-related side effects and hypokalemia (Chopra et al. 1991; Collette et al. 1991; de Marie et al. 1994; Jangnegt et al. 1995). Acute dyspnea has also been reported in a few patients (Arning et al. 1995). Although these lipid preparations are less toxic than amphotericin B deoxycholate, it appears that on a milligram per milligram basis they are less potent (Collette et al. 1991; Meunier et al. 1991; Schmitt 1993; de Marie et al. 1994; Jangnegt et al. 1995). Doses of 3–5 mg/kg of liposomal forms of amphotericin B are well tolerated and commonly used (Collette et al. 1991; Meunier et al. 1991; Schmitt 1993; de Marie et al. 1994; Jangnegt et al. 1995). These preparations are all efficacious (Chopra et al. 1991; Ringden et al. 1991; Mills et al. 1994; Viviani et al. 1994). Comparative studies with amphotericin B deoxycholate are now emerging. The first such report, comparing amphotericin B lipid complex (ABLC) 5 mg/kg/day with amphotericin B 0.6 mg/kg/day for candidiasis, found comparable responses, with less renal toxicity in the ABLC-treated patients (Anaissie et al. 1995b).

All are effective antifungal agents for a variety of mycoses, including *Candida* species, *Aspergillus*, *Fusarium*, *Cryptococcus neoformans*, and others (Anaissie and Ramphal 1992; Jangnegt et al. 1995; Tollemar and Ringden 1995; Walsh et al. 1997; White et al. 1997; Graybill et al. 1998b). These agents have also been used for empirical therapy for potential mycoses in the febrile neutropenic patient. Here it appears that AmBisome is superior to amphotericin B, whereas Amphotec is only equal (Walsh et al. 1998; White et al. 1998). Anecdotal data are accumulating that high doses ($\geqslant$5 mg/kg/day) of lipid amphotericin B preparations may be more efficacious than amphotericin B deoxycholate for the treatment of invasive zygomycosis, and some would suggest that these agents be considered as first line therapy for these refractory infections (Gonzalez et al. 2002; Mondy et al. 2002). The very high costs of lipid preparations (up to US$1 000 per day) may preclude their widespread use for indications such as empirical therapy, though pharmacoeconomic analyses point out that this may be offset by reducing the costs associated with renal dysfunction and other toxicities attributed to standard amphotericin B (Graybill 1996; Hann and Prentice 2001; Ostrosky-Zeichner et al. 2003).

Flucytosine

This is the only antifungal compound of its kind. Flucytosine is activated by deamination within fungal cells to

Table 2 *Characteristics of lipid-associated amphotericin B*

Drug	Form	Percentage amphotericin	Dose (mg/kg)
Amphotericin B lipid complex	Ribbons	33	Up to 5
Amphotericin B colloidal dispersion	Disks	50 (molar)	Up to 7
Amphotericin B liposomes	Small unilamellar vesicles (SUV)	10	Up to 5
Amphotericin B + Intralipid	Micelles	30	Up to 1.5

the antimetabolite 5-fluorouracil. Flucytosine is highly water soluble and can be given orally or intravenously, although the intravenous preparation is not widely available (Francis and Walsh 1992). Flucytosine is nontoxic in in vitro assays to mammalian cells, but more than one-third of patients treated with this drug experience bone marrow depression and gastrointestinal intolerance. The toxicity of flucytosine in vivo is thought to be mediated by bacterial conversion intraluminally, in the gut, of flucytosine to 5-fluorouracil, a compound with significant human toxicity (Harris et al. 1986). Flucytosine has a narrow spectrum aimed largely at yeasts, including *Candida* spp. and *Cryptococcus neoformans* (Tassel and Madoff 1968). Some activity has been reported against *Aspergillus* spp. and some agents of chromoblastomycosis (Vandevelde et al. 1972). Flucytosine has been used as monotherapy for treatment of cryptococcosis, but resistance emerged rapidly and only 10 (43 percent) of 23 evaluable patients had a response to therapy (Hospenthal and Bennett 1998). Flucytosine is subject to development of resistance by mutation of cytosine permease, deaminase, and other mechanisms (Francis and Walsh 1992). Thus, flucytosine is used clinically only in combination with amphotericin B and, more recently, fluconazole (Larsen et al. 1994). Flucytosine is excreted largely unchanged by the kidneys. Renal failure, commonly induced by amphotericin B, causes an increase in plasma concentrations of flucytosine which potentiates its toxicity. Some clinicians have argued that serum concentrations should be measured on all patients receiving flucytosine, but others have found that monitoring leukocyte counts and creatinine, and adjusting doses based on these parameters, is sufficient to minimize intolerance. This has best been demonstrated in a study of cryptococcosis, wherein 2 weeks of amphotericin B was compared with and without flucytosine. If dosing was adjusted for renal and bone marrow function, toxicity was not sufficient to remove or exclude many patients from the study (Van der Horst et al. 1997).

Azoles

All of the azole antifungal agents act by inhibiting fungal cytochrome 14α-demethylase (Table 1) (Vanden Bossche 1985). Inhibition of this enzyme blocks synthesis of ergosterol for fungal cell membranes. Consequently, the integrity of membrane-associated oxidative enzymes is impaired, with accumulation of phospholipids within the cell and ultimately cell death. The action of antifungal azoles takes several generations of fungi to become apparent and is consequently much slower than that of the polyenes.

Differences among antifungal azoles are primarily in their pharmacokinetics, and in the relative avidity of the drug for fungal versus mammalian enzymes (Tables 3, 4, 5, and 6). In distinction to the drugs developed initially, fluconazole and itraconazole have a vastly increased affinity for fungal membranes over mammalian cell membranes, and are better tolerated than ketoconazole (Table 5) (Como and Dismukes 1994). Pharmacokinetics distinguish two general classes of azole antifungals (Table 3). Fluconazole is the only representative of the first group available for therapeutic use at the present time. It is relatively water soluble, is absorbed extremely well, distributed to all tissues, and is excreted largely unchanged by the kidneys (Humphrey et al. 1985). There are relatively few side effects with fluconazole as compared with ketoconazole and itraconazole, the other azoles commonly used (Table 6) (Lazar and Wilner 1990; Como and Dismukes 1994). However, fluconazole is less potent than other azoles against many fungi and its spectrum of activity is confined largely to yeasts (Table 4). Fluconazole is 10–100 times less potent than itraconazole against many species, including *Penicillium marneffei*, *Aspergillus* spp., and some *Candida* spp. (Drouhet 1993; Supparatpinyo et al. 1993). Fluconazole is remarkably well tolerated even when given at doses as high as 2000 mg/day (Anaissie et al. 1995a).

Ketoconazole and itraconazole share several pharmacokinetic parameters (Brass et al. 1982; Heykants et al. 1982, 1989; Daneshmend et al. 1984; Hardin et al. 1988; Barone et al. 1993) (Tables 3, 4, and 5). They are both absorbed optimally in the gastric acid environment, and are cleared by the liver via cytochrome P450-mediated degradation (Table 3). In achlorhydric patients, absorption of these drugs is markedly decreased (Chin et al. 1995). Itraconazole has recently been reformulated in a solution with β-hydroxy-cyclodextrin. This allows intravenous administration and also improves oral absorption of the drug by >60 percent. Further, the pH-associated absorption is no longer an effect, and the drug is best absorbed when taken in a fasting state (Reynes et al. 1997; Vandewoude et al. 1997; Barone et al. 1998). Itraconazole solution is as effective as fluconazole for treatment of esophagitis and thrush, and topical effect may allow treatment of mucosal candidiasis even when patients are taking rifampin. Coadministration of drugs such as rifampin (rifampicin), rifabutin, or carbamazepine, which induce hepatic drug-metabolizing enzymes, causes itraconazole or ketoconazole serum concentrations to fall, and may be associated with treatment failure (Tucker et al. 1992; Como and Dismukes 1994). Alternatively, itraconazole and ketoconazole may cause elevations of serum concentrations of other drugs by competing for the same site that is degraded by the same hepatic enzymes. Such

drugs include ciclosporin, digoxin, coumadin (warfarin), terfenadine, and astemizole, and may include oral sulfonylureas (Kramer et al. 1990; Crane and Shih 1993; Pohjola et al. 1993; Sachs et al. 1993; Como and Dismukes 1994) (Table 6).

Itraconazole is in general more potent than ketoconazole or fluconazole, has a broader spectrum, and may be used to treat infections with *Aspergillus* spp. (Table 4) (Denning et al. 1989). Itraconazole is much better tolerated than ketoconazole. Ketoconazole binds more avidly to mammalian cells than itraconazole, and causes hepatotoxicity in up to 5 percent of patients (Sugar et al. 1987), whereas hepatotoxicity is rare with itraconazole. Ketoconazole also suppresses synthesis of testosterone and, at high concentrations, cortisol (Table 5) (Pont et al. 1982, 1984). Itraconazole in high doses causes edema, hypokalemia, and hypertension (Sharkey et al. 1991). All three azole compounds, when given at high doses for a prolonged time, may cause alopecia.

The doses of all three azole drugs are 200–400 mg/day, although higher doses of fluconazole appear well tolerated and may be more effective. The half-life of ketoconazole is less than 12 hours, and only at doses above 400 mg/day is there an accumulation from one day to the next. As a result of slow clearance, with more than a 24-hour half-life, there is accumulation over 2 weeks for itraconazole and fluconazole to reach a steady state (Hardin et al. 1988; Como and Dismukes 1994). Some recommend using 300 mg twice daily for 3 days as a 'loading dose'(for itraconazole, and an initial dose twice that of a daily dose for fluconazole)(Wheat et al. 1995). As yet, there is no clear correlation between clinical response and serum concentration, but serum concentration of itraconazole should be measured several days after starting treatment, especially if the patient is seriously ill; this indicates that the drug has been absorbed.

In neutropenic patients fluconazole has been used at 400 mg/day for empirical therapy or prophylaxis of fungal infections. Inherently resistant species that are not *Candida albicans*, such as *Candida glabrata* and *Candida krusei*, may emerge in that setting (Goodman et al. 1992; Rex et al. 1995b). In patients infected with the human immunodeficiency virus (HIV) with severe immune deficiency, fluconazole is the mainstay of treatment for thrush. However, long courses and low-dose exposure to fluconazole are associated with emergence of resistance to *C. albicans* (Heinic et al. 1993; Redding et al. 1994; Rex et al. 1995b). The antifungal spectrum of the antifungal azoles is broadest for itraconazole, which is effective against *Aspergillus* spp., *P. marneffei*, and many *Candida* spp. resistant to fluconazole (Denning et al. 1992; Supparatpinyo et al. 1992, 1993; Barchiesi et al. 1994a). In non-HIV-infected patients with candidemia, there has been a change from *C. albicans* to non-*albicans Candida* spp., such as *C. glabrata* and *Candida tropicalis*. These are more resistant to fluconazole. However, against fluconazole-resistant *Candida* spp. isolates, the potency of itraconazole is somewhat less than against fluconazole-susceptible isolates (Barchiesi et al. 1994a).

At present there are no indications that azoles have cumulative toxicity. Fluconazole has been used at 400–800 mg/day for treatment of fungal meningitis for years, and for shorter times up to 2 000 mg/day have been used with no major adverse sequelae (Berry et al. 1992; Galgiani et al. 1993). As fluconazole is excreted largely unchanged by the kidneys, it accumulates in renal failure. Other antifungal azoles are degraded by hepatic cytochrome P450 enzymes and have a number of important drug interactions (Table 6). Maximal chronic dosing of itraconazole tolerance is probably in the range of 600–800 mg/day, and is mediated by gastrointestinal intolerance and a curious phenomenon of hypotension,

edema, and hypokalemia (Sharkey et al. 1991). No endocrine or renal cause for this phenomenon has been identified. Ketoconazole toxicity is mediated by gastrointestinal intolerance, cortisol suppression, and testosterone suppression at levels of 1 200 mg/day or more (Pont et al. 1984).

Voriconazole is the first of the second generation triazole antifungals, which includes posaconazole and ravuconazole (Johnson and Kauffman 2003). These agents are potent, broad-spectrum agents which were developed specifically to target molds, especially *Aspergillus*, and yeasts other than *C. albicans*, that may exhibit resistance to the earlier triazoles, fluconazole, and itraconazole (Sheehan et al. 1999).

Voriconazole is active in both oral and parenteral formulations and has been extensively evaluated in clinical trials for a wide range of fungal pathogens. In vitro, voriconazole demonstrates fungicidal activity against many strains of *Aspergillus*, including *Aspergillus fumigatus* (Espinel-Ingroff et al. 2001). It also demonstrates activity against *Aspergillus terreus*, which may be resistant to amphotericin B, although MICs to voriconazole may be increased (Walsh et al. 2003). The broad spectrum of activity extends to other molds such as *Fusarium* and *Scedosporium*, and includes agents of pheohyphyomycosis, such as *Bipolaris*, *Scedosporium*, *Alterneria*, and others, but not the zygomycetes (Pfaller et al. 2002). Notably, excellent in vitro and animal model data support its potent activity against *C. krusei* as well as *C. glabrata*, although susceptibility may be less for the latter, particularly when the strains are fluconazole resistant (Pfaller et al. 2003a). Except for *C. krusei*, generally a linear relationship exists between fluconazole and voriconazole, with MICs being approximately 100-fold lower for voriconazole, although breakpoints have yet to be established.

Clinical studies have documented superior efficacy and better tolerance of voriconazole as compared to standard amphotericin B for the treatment of invasive aspergillosis so that voriconazole should be considered for primary therapy for most patients with invasive aspergillosis (Denning et al. 2002; Herbrecht et al. 2002). Improved outcomes were also demonstrated in patients with extensive infection, including central nervous system infection (Troke et al. 2003). For rare and refractory molds, such as *Fusarium* and *Scedosporium*, results have also been favorable with successful outcomes reported in 30–40 percent of patients failing other antifungal therapies (Walsh et al. 2002a; Perfect et al. 2003). Clinical data are less extensive for serious *Candida* infection, although good efficacy and safety was demonstrated in patients with *Candida* esophagitis (Ally et al. 2001). Additional clinical data for candidemia are in progress. In an open labeled trial comparing voriconazole to liposomal amphotericin B for fever in patients with neutropenia, voriconazole was less successful at achieving overall success, but importantly was more effective at reducing the clinically relevant endpoint of breakthrough fungal infections, particularly *Aspergillus* (Walsh et al. 2002b).

The safety of voriconazole has been favorable in clinical trials of patients with serious fungal infections (Herbrecht et al. 2002; Walsh et al. 2002a). The most common serious adverse event has been a transient and reversible visual toxicity that has not been associated with pathology and is rarely dose limiting (Johnson and Kauffman 2003). This effect occurs after oral or intravenous administration and likely correlates with higher serum levels and occurs in approximately 30 percent of patients, generally 30 minutes after administration, and lasts for a mean of 30 minutes. Other less common events include liver toxicity in 10–15 percent, skin rash, nausea, and vomiting.

Voriconazole achieves CSF levels of approximately 50 percent that of serum but little (<5 percent) active drug is excreted in the urine. A loading dose of 6 mg/kg every 12 hours for two doses is recommended for initial therapy intravenously, followed by 4 mg/kg twice daily for invasive aspergillosis and molds for which the drug is indicated in the USA. Oral therapy is recommended at 200 mg twice daily. The drug is metabolized through the cytochrome P450 enzyme system so that drug interactions and variability in patient metabolism can occur (Groll et al. 2003). Metabolism occurs most extensively through CYP2C19, which demonstrates genetic variability, so that some patients such as non-Indian Asians may have higher drug levels. CYP3A4 and other isoenzymes generally contribute less to its metabolism. Drug interactions are common including those with immunosuppressive agents. Dose reductions of ciclosporin by half and tacrolimus by one-third are advised along with close follow-up of the immunosuppressive drug level and for clinical toxicity. Sirolimus is contraindicated because of the dramatic increase in those levels that can occur. Importantly, the immunosuppressive drug dosage will need to be increased after voriconazole is discontinued.

A major issue is whether the azoles and amphotericin B are antagonistic when used together. There is some suggestion, in animal models, that this may be the case in aspergillosis and candidiasis (Polak et al. 1982; Schaffner and Frick 1985). Sugar argues that fluconazole is water soluble, can pass readily into the fungal cell, and may act at a site distant from the cell membrane site of amphotericin B (Sugar 1995). Thus there is no antagonism, and there may even be an additive effect of fluconazole and amphotericin B. In a large study comparing fluconazole alone versus fluconazole with amphotericin B for treatment of candidemia, no clinical antagonism was observed, and there was a trend actually favoring the combination (Rex et al. 2003). Conversely, the lipid-soluble triazoles may concentrate in the cell membrane and act at a site or in a way that antagonizes polyenes, though clinical data are sparse.

Echinocandins

A unique mechanism of action sets the echinocandins apart from other antifungals. Echinocandins are semisynthetic cyclic glycopeptides that inhibit fungal 1,3-β-glucan synthase, which is necessary for the production of 1,3-β-glucan, a major component in many fungal cell walls (Hector 1993; Kurtz et al. 1994a; Abruzzo et al. 1995; Bartizal et al. 1995). Along with chitin and mannans and mannoproteins, glucans make up the major components of the fungal cell wall. The cell wall is responsible for maintaining integrity of the cell shape, for ion and small molecule exchange between the cell and its milieu, and for presentation of surface molecules. 1,3-β-Glucan synthase is an attractive target because it is not present in mammalian cells. This class of drugs appears to have no nephrotoxicity and minimal hepatotoxicity. However, oral absorption is poor and parenteral administration is required. In vitro studies and animal model studies have confirmed great potency in candidiasis and aspergillosis (Abruzzo et al. 1995). *Cryptococcus neoformans*, which contains mostly 1,6-β-glucans in its cell walls, is resistant.

A stop-and-start phase of initial development ultimately led to the first derivative, cilofungin (Lilly). Cilofungin failed in phase I clinical trials because it required a vehicle for aqueous solubilization which turned out to be nephrotoxic. Also limiting cilofungin was the perceived narrow antifungal spectrum, which was largely limited to *Candida*. This class of drugs was at one time close to being discarded because of narrow spectrum and very poor oral absorption. However, persistent efforts on the part of several pharmaceutical companies have led to the licensing of caspofungin (Merck), and late phase II trials with two other contenders, micafungin (Fujisawa) and anidulafungin (Vicuron). The rapid development of echinocandins and their introduction into clinical practice has been nothing short of spectacular. Indeed, the advent of echinocandins is one major reason why Ostrosky-Zeichner et al. were recently able to sound the death knell for amphotericin B desoxycholate (Ostrosky-Zeichner et al. 2003).

The action of echinocandins is very rapid, occurring in minutes, and is noncompetitive (Uzun et al. 1997; Karlowsky et al. 2001). Echinocandins bind to the fungal cell sites where cell wall synthesis is most active. In yeast cells, such as *Candida* spp., echinocandins bind to the cell in many places, and diffusely affect cell wall synthesis. As a result, the fungal cell collapses, resembling an erythrocyte, and may die. Against *Candida*, echinocandins have a very prolonged post-antifungal effect, and are considered fungicidal in vitro (Ernst et al. 2000). In contrast to yeasts, the activity of echinocandins in filamentous fungi is concentrated at the hyphal tip and the budding sites (Kurtz and Rex 2001; Bowman et al. 2002). Supravital stains have shown that echinocandins are more or less fungistatic against *Aspergillus* (Kurtz et al. 1994b). Part of the fungal mycelium is destroyed, but not all of it.

The antifungal spectrum of echinocandins appears to be similar for caspofungin, anidulafungin, and micafungin. These agents are broadly effective in vitro and in animal models against *Candida* spp., including fluconazole-susceptible or resistant isolates (Nelson et al. 1996; Graybill et al. 1997; Zhanel et al. 1997; Petraitiene et al. 1999; Abruzzo et al. 2000). It does not appear at present that the higher MIC values reported for caspofungin against *Candida parapsilosis* are reflected in clinical failures (Mora-Duarte et al. 2002). There is more varying activity against molds, where a new test, the minimal effective concentration (MEC), appears more useful (Oakley et al. 1998). Most *Aspergillus* spp. and some other molds, such as certain species of phaeohyphomycetes, appear to be susceptible, while zygomycetes and *Trichosporon beigelii* are resistant (Espinel-Ingroff 1998; Del Poeta et al. 1996). *Coccidioides immitis* is susceptible, while there are conflicting reports of *H. capsulatum* (Graybill et al. 1998a; Kohler et al. 2000; Gonzalez et al. 2001). The in vitro antifungal spectrum has been most widely explored for caspofungin, and we are assuming that the other echinocandins are similar. The limited data in vitro and in animals have acted to delay clinical exploration of these compounds in mycoses other than *Candida* and *Aspergillus* infections. There is a recent report of a patient with breakthrough *T. beigelii* infection while receiving caspofungin, which suggests resistance (Goodman et al. 2002). The full range of activity of echinocandins has yet to be elucidated. Because the target is unique to fungi (with little toxicity to mammalian cells), the echinocandins are thought to be excellent candidates to replace the more toxic conventional amphotericin B – at least against a few major pathogens.

All three echinocandins now in clinical use or trials share characteristics of water solubility and poor oral absorption. Thus all drugs must be administered intravenously. Although there have been concerns of histamine-like reactions following intravenous infusion, these have been rare. There are some differences among the drugs, but it is not yet clear whether these will impact on clinical use (Table 7). The slower clearance of anidulafungin, as well as its clearance entirely by chemical, not metabolic, degradation, may allow for less frequent dosing. The lower protein binding of anidulafungin (86 versus >95 percent for caspofungin and micafungin) may also influence the ultimate determination of in vitro breakpoints.

It is thought that the peak serum concentration/MIC ratio determines effect of echinocandins. This is similar to amphotericin B, but in contrast to fluconazole, where the AUC/MIC ratio appears more important (Andes 2003). With very few serious adverse reactions to the echinocandins (though data are much more extensive with caspofungin), the maximum tolerated dose and the

Azuma et al. (1998); Stone et al. (2002); Dowell et al. (2003).

therapeutic ratio have not been determined (Arathoon et al. 2002; Mora-Duarte et al. 2002; Letscher-Bru and Herbrecht 2003). Caspofungin and anidulafungin have adverse effects similar to fluconazole (Villanueva et al. 2002; Krause et al. 2003).

The major clinical uses of echinocandins are being defined. All three drugs are effective against *Candida* mucosal infection, with responses similar to fluconazole. A dose of 50 mg/day appears to be effective, given for up to 2 weeks for patients with esophagitis (Kohno et al. 2001; Arathoon et al. 2002; Krause et al. 2003). The only large study with systemic candidiasis was caspofungin versus amphotericin B, and found that both drugs were similarly effective, between 65 and 75 percent, but that caspofungin had far fewer adverse reactions (Mora-Duarte et al. 2002). Caspofungin is also effective in mucosal infection caused by fluconazole-resistant *Candida* (Kartsonis et al. 2003). For fluconazole-resistant *Candida* in the bloodstream, caspofungin is now considered the drug of choice (Walsh 2002).

Studies of aspergillosis are generally unpublished and open label, salvage trials (Maertens et al. 2000). Caspofungin is as effective as a variety of other alternatives. Data with micafungin and anidulafungin are spotty. Micafungin has been compared with fluconazole for antifungal prophylaxis. Results are equivalent to fluconazole, but unfortunately not quite superior to fluconazole against *Aspergillus*. Animal data suggest that there may be additive effects of micafungin and a triazole against *Aspergillus* (Petraitis et al. 2003). Clinically, there are only a few collections of anecdotes, and these are not helpful.

Overall, clinical experience has been restricted to some comparative trials with mucosal candidiasis, one large study with disseminated *Candida*, and unpublished data on prophylaxis and aspergillosis. Beyond candidemia, the roles of the echinocandins have yet to be defined.

FUTURE ANTIFUNGAL DRUGS

New triazoles are under consideration, including posaconazole (Schering, NJ, USA). These agents are much more lipid soluble than fluconazole, have an increased fungal spectrum against fluconazole-resistant *C. albicans*, other *Candida* spp., and molds (Atkinson et al. 1994; Hoffman et al. 2000), and are excreted primarily by hepatic degradation. Hepatic metabolism places them at potentially similar risks of drug reaction as ketoconazole and fluconazole. Although these drugs have increased activity against fluconazole-resistant *Candida* spp., the MIC is higher than for fluconazole-sensitive isolates.

Other antifungal targets are being explored. These include elongation factor 2, chitin synthases, topoisomerase, translation, myristoylation, and steps specific to certain fungi, such as phenyloxidase and capsule synthesis for *Cryptococcus neoformans*. Agents aimed at these new targets have not yet reached clinical trials. Finally, there are numerous in vivo animal studies examining combined antifungal drugs and immune modulators, such as phagocyte colony-stimulating factors, interferons, and interleukins (Rex et al. 1991; Uchida et al. 1992; Ausiello et al. 1993; Brummer and Stevens 1994; Brummer et al. 1994; Joly et al. 1994; Nassar et al. 1994; Roilides et al. 1994, 1995; Sewell et al. 1994; Vitt et al. 1994). The potential clinical value of these cytokine/antifungal combinations has not been clearly defined.

ANTIFUNGAL SUSCEPTIBILITY TESTING

The combined effects of increasing numbers of fungal infections, growing numbers of patients at risk, the increasing rate of fungal resistance, and the expanded antifungal armamentarium have led to an increased recognition of the need for standardized laboratory testing for antifungal drug susceptibility. However, numerous problems have been encountered in the quest for a simple, reproducible, and inexpensive testing system applicable to all clinically important fungi. These include multiple variables affecting outcome, such as pH, inoculum size, medium, and time and temperature of incubation, which produce varying results; unclear in vitro to in vivo correlation; and differences in testing yeasts versus filamentous fungi (Rex et al. 1993). Several excellent reviews have been written on the subject, which detail the difficulties in developing in vitro

antifungal susceptibility testing and insights into controversial issues (Stevens 1984; Drutz 1987; Galgiani 1987, 1993; Espinel-Ingroff and Shadomy 1989; Pfaller and Rinaldi 1993; Rex et al. 1993, 2001; Sheehan et al. 1993; Pfaller et al. 1997; Pfaller and Yu 2001; Rex and Pfaller 2002).

Early studies

Only recently has antifungal drug susceptibility testing become an important issue. Initially, amphotericin B was the only agent available for systemic infection, so testing did not appear to have practical clinical significance. Even after several antifungal agents became available, only a few laboratories were performing antifungal testing, usually less than 10–20 isolates per year (Rex et al. 1993). Studies in the 1980s revealed that between-laboratory susceptibility results varied by as much as 512-fold, and standard methods were not available for susceptibility testing (Rex et al. 1993). It was noted, however, that the rank order of isolates was relatively consistent among the different laboratories, suggesting a definite need for standardized methods.

Many techniques have been used to determine antifungal susceptibility, including measurement of germ tubes, uptake of metabolites, flow cytometry, agar-based methods, and broth dilution (Rex et al. 1993). Most are considered impractical for large-scale use. Agar techniques are appealing because of their ease and low cost, but suffer from a wide variation of results, including factors such as inoculum size, temperature, time of incubation, and ability of poorly soluble drugs, such as ketoconazole and itraconazole, to diffuse through agar (Rex et al. 1993). Broth dilution methods are widely used, and have been standardized by the National Committee for Clinical Laboratory Standards (NCCLS) for testing of *Candida*, *Cryptococcus* (document M-27A), and a variety of clinically important filamentous fungi (document M-38A) (National Committee for Clinical Laboratory Standards 1997, 2002).

Factors affecting antifungal susceptibility testing

END-POINT DETERMINATION

This aspect of antifungal testing is an important source of variability among laboratories in the testing of azoles and occasionally 5-flucytosine. These agents are generally fungistatic and usually tend not to have distinct end points on MIC testing, and thereby introduce subjective interpretations of susceptibility results. By contrast, amphotericin B, which is fungicidal, generally produces distinct end points. Azoles in particular may also produce 'trailing end points,' with growth evident at all concentrations tested (Rex et al. 1993). A solution to quantify end-point determination has been proposed by the NCCLS method, which uses an 80 percent decrease in turbidity as compared with control to establish an end point. A study by Pfaller et al. (1995) demonstrated that agitation of a microbroth well or spectrophotometric measurement led to a more definitive end point. More recently, studies have suggested that a 50 percent end point may lead to fewer trailing end points and may better predict clinical outcome (St Germain 2001; Arthington-Skaggs et al. 2002). Isolates that are susceptible at 24 hours but resistant at 48 hours due to trailing appear to revert to susceptible at lower media pH, and actually behave as if they are susceptible in vivo (Revankar et al. 1998b; Rex et al. 1998; Marr et al. 1999). Further clinical studies are needed with these isolates.

For testing echinocandins, a unique end point termed the MEC has been proposed that addresses the difficulties in assessing response to the drug, particularly for filamentous fungi (Oakley et al. 1998).

INOCULUM SIZE

It has been shown that increasing the size of inoculum can drastically increase MICs for most drugs tested, and interlaboratory consistency is improved by using smaller inocula (Rex et al. 1993). The NCCLS method for yeasts suggests an inoculum of $0.5–2.5\times10^3$ c.f.u./ml, prepared by matching turbidity at 530 nm of a 0.5 McFarland standard (National Committee for Clinical Laboratory Standards 1997). For filamentous fungi, NCCLS recommends an inoculum of $0.4–5\times10^4$ c.f.u./ml, by spectrophotometric measurement, with varying optical densities depending on the species tested (National Committee for Clinical Laboratory Standards 2002).

Hemocytometer count is also a reasonable technique for preparing an inoculum, although with results that are less consistent in between-laboratory tests (Rex et al. 1993). In comparing a wide variety of filamentous fungi, this method may be more reliable, though it is unclear if this would significantly affect the results of susceptibility testing compared with the standardized method (Aberkane et al. 2002).

INCUBATION

Both time and temperature can have significant effects on MIC determinations. MICs generally tend to increase with longer incubation periods (Rex et al. 1993). Temperature variations are not as predictable, but are felt to be least apparent at 35°C (Rex et al. 1993). The NCCLS methods recommend incubation at 35°C for 48 hours for *Candida* spp., 72 hours for *Cryptococcus* spp., and 24–72 hours for molds, depending on the species (National Committee for Laboratory Standards 1997, 2002).

MEDIA

Different media can give rise to widely varying results of antifungal testing, due to interactions between the drugs and the testing media. This can be especially seen with relatively undefined media. The pH can also be important, with a lower pH of the test medium associated with higher MICs of most antifungal agents. For this reason, the use of a defined, synthetic medium, RPMI-1640 (Sigma Chemical Company, St Louis, MO, USA), pH 7.0 with 3-[*N*-morpholino]-propanesulfonic acid (MOPS) (Sigma) is advocated by NCCLS for both yeasts and filamentous fungi (National Committee for Clinical Laboratory Standards 1997, 2002).

Testing of filamentous fungi

Until recently, no standardized method for antifungal susceptibility testing of filamentous fungi was available. This area of susceptibility testing presents its own, unique problems, namely how to quantify inhibition of growth for organisms that change morphological forms. For example, *Aspergillus* spp. have conidia, which are small sphere-like forms that are easily quantifiable, but germinate to hyphal forms that are not. Many studies have used germination of hyphal growth as an indicator in susceptibility testing. Denning et al. (1992) found a wide range of in vitro susceptibility results while reviewing studies by different investigators, although within their own laboratory they achieved consistent results. In response to these issues, the NCCLS developed M-38A, a standardized broth dilution method for susceptibility testing of filamentous fungi (National Committee for Clinical Laboratory Standards 2002). The primary differences with the yeast testing method are variable incubation times for different species and a no growth or 100 percent inhibition end point for amphotericin B, itraconazole, and the newer azoles. Other methods have also been studied, including E-test, automated blood culture systems, and colorimetric methods, which in general have had good correlation with the broth method, particularly the E-test (Espinel-Ingroff 2001; Meletiadis et al. 2001; Rath et al. 2002; Pfaller et al. 2003b). In addition, the concept of minimum fungicidal concentration (MFC) may be important for in vitro–in vivo correlation, and a proposed definition is the lowest dilution with <3 c.f.u. on subculture, corresponding to 99–99.5 percent killing based on the NCCLS standardized inoculum (Espinel-Ingroff et al. 2002).

METHODS OF SUSCEPTIBILITY TESTING

Macrobroth dilution

This is the currently approved reference method for antifungal susceptibility testing of yeasts and filamentous fungi. Numerous studies have shown good correlation between laboratories using this methodology: amphotericin B, 90 percent; ketoconazole, 75 percent, 5-flucytosine, 85 percent; fluconazole, 88 percent (Rex et al. 1993). However, the NCCLS broth technique is insensitive for detecting resistance to amphotericin B (Rex et al. 1993). The current recommendation uses a macrobroth technique with 1 ml of medium, but microbroth dilution using 0.2 ml in a 96-well microtiter plate may be more practical for rapid, widespread use, and appears to produce similar results (Barchiesi et al. 1994b; Pfaller et al. 1994a; Sewell et al. 1994; Hacek et al. 1995). It is considered an acceptable alternative to the standardized method by the NCCLS.

Colorimetric

ALAMAR BLUE

Alamar Blue (Alamar Biosciences, Inc., Sacramento, CA) is a novel colorimetric indicator that changes color from blue to red when reduced in the presence of microbial growth (Pfaller and Barry 1994). It has shown excellent correlation with bacterial reference methods and several studies have shown promise in antifungal susceptibility testing (Pfaller and Barry 1994; Pfaller et al. 1994a, b; Tiballi et al. 1995; To et al. 1995). In general, studies have confirmed that results agree closely with the NCCLS macrobroth method at 24 hours and less so at 48 hours (Pfaller and Barry 1994; Pfaller et al. 1994b; To et al. 1995). Some combinations, such as fluconazole with *C. albicans*, *C. glabrata*, and *C. tropicalis*, had relatively poor correlations (11–65 percent) in one study (To et al. 1995). A commercial system, Sensititre YeastOne (TREK Diagnostics Systems Inc., Westlake, OH) which uses Alamar Blue, was recently approved by the FDA. Studies using this system have shown good correlation with the NCCLS method, though some drug-species combinations have less correlation than others (Espinel-Ingroff et al. 1999; Morace et al. 2002).

TETRAZOLIUM SALTS

A tetrazolium salt, 2,3-bis-2-methoxy-4-nitro-5-sulphophenyl-5-[phenylaminocarbonyl]-2*H*-tetrazo-lium hydroxide (XTT), has been used in eukaryotic cell drug assays (Tellier et al. 1992). It is a member of a class of compounds that produce a colored formazan crystal when reduced, which can be detected using a spectrophotometer (Tellier et al. 1992). A study by Tellier et al. (1992) used this agent to test various yeast species, and distinct MICs were observed, although this method was not directly compared to the NCCLS reference method.

Another tetrazolium derivative, 3-4,5-dimethyl-2-thiazolyl-2,5-diphenyl-2*H*-tetrazolium bromide (MTT), was used to determine antifungal susceptibility in a study by Jahn et al. (1995). It demonstrated reasonable

correlation to NCCLS macrobroth methods, but few isolates were tested.

E-test

This method of susceptibility testing has been used successfully with bacteria. It involves use of a plastic strip impregnated with a defined gradient of the antimicrobial agent to be tested. The strip is then placed on agar seeded with the test organism. The graded zone of inhibition, if present, is read from a scale printed on the strip, corresponding to the particular concentration of drug. Multiple studies have shown that good correlation is achieved with the NCCLS method with amphotericin B, azoles, and caspofungin, though occasional problems were noted. A study by Colombo et al. (1995) comparing the E-test and NCCLS macrobroth methods showed reasonable MIC correlations, with 71 percent for ketoconazole, 80 percent for fluconazole, and 84 percent for itraconazole. However, the E-test results were usually one- to twofold less than for the NCCLS method, with *C. tropicalis* showing the least concordance (Colombo et al. 1995). Another study by Sewell et al. (1994) demonstrated similar findings, with poor correlations against NCCLS methodology for *C. tropicalis* and *C. glabrata* at 24 and 48 hours. *C. albicans* testing was in good agreement with NCCLS at 24 hours, but not at 48 hours (Sewell et al. 1994).

Other methods

Alternative testing methods that may be easier to perform and interpret than the NCCLS method continue to be evaluated and show promise. These include use of flow cytometry (results within 6 hours), automated blood culture systems, disk diffusion, and sterol quantitation (Ramani and Chaturvedi 2000; Arthington-Skaggs et al. 2002; Rath et al. 2002; Matar et al. 2003). In addition, testing of *Candida* spp. in the presence of biofilms has been studied to better evaluate the effect of antifungal drugs in this setting (Ramage et al. 2001). Agar dilution screening for *Candida* and *Cryptococcus* has also shown promising results compared with the NCCLS macrobroth method, and may be useful to rapidly detect clinical resistant isolates (Patterson et al. 1996; Kirkpatrick et al. 1998; Nelson and Cartwright 2003).

IN VIVO–IN VITRO CORRELATION

Many studies have shown a disparity between in vitro MICs and in vivo efficacy for antifungal agents tested. However, standardized methods have improved correlation in more recent studies. There are interpretive breakpoint guidelines for antifungal susceptibility testing of fluconazole and itraconazole to *Candida* spp. (Rex et al. 1997). These were primarily based on studies of the correlation between in vitro testing and clinical response in oropharyngeal candidiasis in HIV-infected patients (Laguna et al. 1997; Revankar et al. 1998a). Correlations between increased MICs of *C. albicans* to fluconazole and poor clinical response in oropharyngeal candidiasis have been shown (Redding et al. 1994; Revankar et al. 1998a). Studies of systemic fungal infections have also shown correlation with in vitro testing (Aller et al. 2000; Kovacicova et al. 2000; Lee et al. 2000). There are also clinical responses when in vitro testing reveals the organism to be resistant. In a study by Rex et al. (1995a), bloodstream isolates from *Candida* spp. revealed an inverse correlation between in vitro resistance to fluconazole at MIC of 32 μg/ml or more and response to therapy at 400 mg/day, suggesting that in this setting other factors may be more important in determining clinical outcome than in vitro susceptibility testing. However, the number of patients with resistant organisms was very small. Increased MICs to amphotericin B to over 0.8 μg/ml were associated with higher mortality in oncology patients in a study by Powderly et al. (1988). In a study by Denning et al., in vitro testing conditions for itraconazole were adjusted to produce good correlation to clinical response with six isolates of *A. fumigatus*, of which two were resistant (Denning et al. 1997). When it occurs, a lack of correlation between in vitro susceptibility and in vivo efficacy may result from host factors or differences in drug pharmacokinetics that alter its availability at the site of infection. In summary, clinical correlation of in vitro activity of antifungal agents is a complex issue that will require ongoing study. There is emerging evidence, however, that in vitro testing will be useful to the clinician.

Principles of antifungal therapy

PETER G. PAPPAS

Prophylactic and preemptive therapy	1	Clinical trial design for antifungal compounds	2
Empiric therapy	2	References	4
Specific therapy	2		

Any discussion of antifungal therapy must begin with a clear understanding of the terminology that describes the strategies for prevention and treatment of invasive fungal infections. Moreover, a basic understanding of the problems inherent to clinical trial design and the challenges in interpretation of clinical trial data involving antifungals is essential for the appropriate clinical application of these therapies. This chapter provides a brief overview of these two important areas.

PROPHYLACTIC AND PREEMPTIVE THERAPY

The terms prophylaxis, targeted prophylaxis, and preemptive are often used interchangeably in conjunction with antifungal therapy. While there is some overlap in meaning, these terms represent different approaches to therapy. Prophylaxis generally refers to the broad use of antifungal therapy in a heterogeneous group of patients who are at variable risk of developing superficial or invasive fungal infection. By definition, prophylactic antifungal therapy is administered to patients who are considered to be at risk for fungal infection, but who have no symptoms of infection at the time that the antifungal agent is initiated. Prophylaxis may be systemic (e.g. oral or parenteral fluconazole) or topical (e.g. oral nystatin). Virtually any population can be given prophylactic antifungal therapy, but it is typically administered to high-risk patient populations including selected medical and surgical intensive care unit (ICU) patients (Eggimann et al. 1999; Garbino et al. 2002), allogeneic hematopoietic stem cell transplant recipients (Winston et al. 2003), and selected solid organ transplant recipients (Winston et al. 1999). The chief aim of antifungal prophylaxis is the prevention of colonization and disease due to target organisms.

Targeted prophylaxis implies a measure of selectivity, that is, utilizing specific risk factors or patient characteristics in determining the population to whom prophylaxis is administered. It is assumed that the target population is uniformly at higher risk of developing fungal infection than patients with similar underlying conditions or severity of illness, and this high-risk population is selected on the basis of certain known risk factors. For example, targeted prophylaxis using fluconazole in the ICU is often administered to patients who have multiple risk factors for invasive candidiasis such as the presence of a central venous catheter, systemic antibacterial therapy, endotracheal intubation, renal failure, and recent abdominal surgery (Garbino et al. 2002). Targeted antifungal prophylaxis with voriconazole is often given to prevent invasive aspergillosis and other mold infections among allogeneic stem cell transplant recipients at risk for graft-versus-host disease.

Preemptive antifungal therapy is administered to persons who are not only at risk but also have markers of early infection, for example, colonization with a fungal pathogen. The group that has been best described in conjunction with preemptive therapy is the liver transplant population who meet criteria for very high risk of invasive fungal infection including prolonged intraoperative time, preexisting renal failure, early colonization with *Candida* spp., retransplant for early graft failure, and choledochojejunostomy anastomosis (Collins et al. 1994).

The optimal use of any form of antifungal prophylaxis or preemptive therapy must utilize a practical and validated assessment of risk. Studies to better define specific risk factors for invasive fungal infection in a variety of clinical settings are essential, recognizing that risk varies substantially between study populations, and that each patient group is characterized by unique conditions that place them at a greater or lesser risk for fungal colonization and disease.

EMPIRIC THERAPY

Empiric antifungal therapy refers to the use of these agents among patients with findings and/or symptoms of suspected invasive fungal disease. The use of empiric antifungal therapy has been studied most extensively in persistently febrile and neutropenic patients (Walsh et al. 1999, 2002; Wingard et al. 2000). The primary goal of empiric antifungal therapy in this setting is to prevent breakthrough fungal infections and to treat baseline infections due to molds and other important fungi in this uniquely susceptible host. However, all neutropenic patients are not alike, and the risk of invasive fungal infection is directly related to the underlying condition(s) and the duration and depth of neutropenia. For instance, induction therapy for acute myelogenous leukemia is associated with a very high rate of invasive fungal infection and associated high mortality, especially due to invasive mold infections. By contrast, myeloablative therapy for most solid tumors usually leads to shorter periods of neutropenia and far less risk of invasive fungal infection. The appropriate use of empiric antifungal therapy in the setting of persistent fever and neutropenia requires that the patient have persistent fever despite a reasonable course (usually 96 hours or more) of broad-spectrum antibacterial therapy, and that there is no other obvious explanation for the clinical deterioration of the patient.

The administration of empiric antifungal therapy to persistently febrile non-neutropenic ICU patients with presumed invasive candidiasis has become common practice in developed countries throughout the world, yet studies that address the appropriateness of this practice and the best approach to therapy are lacking. Several epidemiologic studies have identified multiple risk factors associated with nosocomial candidiasis (Blumberg et al. 2001; Trick et al. 2002; Pappas et al. 2003). Despite the recognition of these risk factors, this group of patients has proven particularly difficult to enroll into clinical trials, and thus, the use of empiric antifungal therapy in the ICU patients with unexplained fever, leukocytosis, hypotension, or other evidence of clinical deterioration is the most common reason to prescribe parenteral antifungal therapy. It remains one of the most poorly understood and understudied areas in the discipline of antimicrobial therapy.

SPECIFIC THERAPY

Specific therapy refers to therapy directed at a specific pathogen which has been detected by culture, histopathology, and/or serology, or in the absence of laboratory evidence, then clinical/radiographic evidence strongly suggestive of invasive fungal disease. These include such findings as hepatosplenic bull's eye lesions suggesting chronic disseminated candidiasis, the halo or air crescent sign on chest CT suggesting invasive aspergillosis, and disseminated cutaneous lesions consistent with invasive candidiasis. Specific therapy is often based on presumptive evidence of infection, but it is nonetheless targeted towards the organism(s) most likely responsible for the clinical picture.

In practice and clinical trials, few infections have received as much attention as candidemia in the non-neutropenic host because of its prevalence and the general familiarity of most clinicians with this entity. Our current practices towards the treatment of candidemia generally reflect the results of large and well-done published comparative clinical trials in this arena (Pappas et al. 2004). Similarly, the treatment of central nervous system (CNS) cryptococcosis has become more uniform because of data generated from therapeutic trials among patients with and without the acquired immunodeficiency syndrome (AIDS) who have CNS cryptococcosis (Saag et al. 2000). By contrast, very few large clinical trials have been done among patients with less common invasive mycoses such as aspergillosis, histoplasmosis, blastomycosis, coccidioidomycosis, and sporotrichosis. Thus, the 'gold standard' of treatment for these mycoses is often based upon data generated from smaller comparative studies without significant power to discern differences in therapeutic outcome.

CLINICAL TRIAL DESIGN FOR ANTIFUNGAL COMPOUNDS

The design and implementation of the clinical trials involving antimycotic agents has been a challenge to clinicians since the availability of amphotericin B in 1958. The key problems encountered in conducting clinical trials of antifungal agents are not dissimilar to those facing the development of other antimicrobial agents; however, these issues have been recently examined in the context of systemic antifungals because of the availability of a growing number of these agents, and the growing difficulties encountered in studying them in a randomized and controlled fashion. The key challenges to the clinical investigator include:

- slow patient accrual because of restrictive eligibility criteria for uncommon diseases
- establishment of meaningful clinical end points
- the absence of validated surrogate markers of success or failure (e.g. serological studies)

- the unwillingness of many investigators to perform double-blinded clinical trials
- the need for large numbers of study centers to facilitate completion of these trials in a reasonable timeframe (Rex et al. 2001).

Patient accrual is an obstacle faced by most clinical trials of anti-infective agents, thus it is not unique to trials of antifungal agents. With the exception of candidemia and possibly CNS cryptococcosis, invasive mycoses are relatively uncommon. Yet, despite the low frequency of most invasive mycoses, the relative lack of effective agents has served as an incentive to place patients into some of these trials for less common mycoses such as histoplasmosis and blastomycosis. By contrast, randomized trials for the treatment of candidemia in non-neutropenic patients have enrolled slowly despite the relatively high incidence of candidemia in the nosocomial setting, reflecting, in part, fairly restrictive entry criteria and an inability to establish a diagnosis consistently within a short timeframe. For example, a recently published candidemia treatment trial enrolled only about 10 percent of all patients with candidemia at study sites (Pappas et al. 2003; Rex et al. 2003). Most of these potentially eligible patients were excluded due to prior antifungal therapy, abnormal laboratory values, age, comorbid conditions, and other considerations. Patient accrual into studies for therapy of invasive aspergillosis has been even more challenging. In a recent open-label trial comparing voriconazole to amphotericin B and other licensed antifungal therapy for the primary treatment of invasive aspergillosis, it required more than 5 years and almost 100 centers to enroll almost 300 eligible patients, again reflecting the effect of restrictive inclusion criteria and the difficulty in establishing a firm diagnosis of an uncommon disorder on patient accrual (Herbrecht et al. 2002).

The reluctance of many investigators to perform nonrandomized trials and the unwillingness of regulatory agencies to accept data from uncontrolled trials for purposes of licensing are other important considerations in the conduct of these trials. Double-blinded studies are difficult to perform, particularly when one of the study arms includes an amphotericin B (AmB) formulation. However, several recent studies have been successfully completed that have successfully blinded both conventional AmB and lipid formulations of AmB (Mora-Duarte et al. 2002; Rex et al. 2003). A randomized and double-blind study comparing AmB in combination with high-dose fluconazole (800 mg/day) to high-dose fluconazole alone for non-neutropenic patients with candidemia, demonstrated that a double-blinded placebo-controlled trial involving AmB can be performed successfully and without undue patient risk (Rex et al. 2003). Similarly, a randomized and double-blinded study comparing AmB to liposomal AmB for empiric antifungal therapy in persistently febrile and neutropenic patients demonstrated the ability to perform a double-blind trial with these agents (Walsh et al. 1999).

Study end points have generated considerable controversy in antifungal trials, relying almost exclusively on mycological (culture), clinical and/or radiographic parameters. Among trials comparing agents for treatment of candidemia, rendering the blood culture negative in conjunction with resolution of clinical signs and symptoms has become a standard end point for a successful outcome. However, clinical end points, including resolution of fever, hypotension, and/or other clinical signs of candidemia, are often difficult to discern due to concomitant illness and other comorbidities that are common among these patients. Thus, in most candidemia studies, an element of investigator bias is introduced in what at first glance might appear to be a fairly 'hard' end point. Similarly, end points for studies of CNS cryptococcosis have utilized a composite end point of cerebrospinal fluid culture negativity at important time intervals such as 2 and 10 weeks, together with the somewhat subjective measurement of clinical improvement based on neurological status and other clinical parameters subject to investigator bias. In both of these examples, the ability to use a surrogate marker of efficacy, such as a serological assay, might have helped improve objectivity and lessen reliance on subjective clinical measurements.

Controversy has surrounded the use of the five-component composite end point utilized in several of the comparative trials of empiric antifungal therapy in persistently febrile and neutropenic patients (Walsh et al. 1999, 2002). The five components include:

1. survival at 7 days after study drug completion
2. no discontinuation of study drug due to toxicity or lack of efficacy
3. prevention of emergence of incident fungal infection
4. successful treatment of baseline fungal infection
5. resolution of fever during antifungal therapy.

To be considered a success in these studies, all five end points must be met. Not surprisingly, these studies have had rates of success that vary between 26 and 50 percent when these criteria are applied stringently. Again, the use of a validated surrogate marker might obviate the need for such complex end points, simplifying outcome assessment by removing such vague and questionable end points as 'fever resolution,' which is prone to much subjective interpretation by investigators.

By necessity, most large antifungal trials require large numbers of participating sites to provide adequate patient accrual, adding another degree of complexity in terms of quality assurance, consistent practice patterns, and variations in interpretation of the protocol.

Despite these important considerations, much progress has been made in the design and implementation of clinical trials of antifungal agents in the last two decades. It will be important in the design and

implementation of future studies to consider each of the challenges, and to strive for more efficient patient selection and more reproducible and timely results.

Resistance to antifungal agents

SEVTAP ARIKAN AND JOHN H. REX

Introduction	1	Mechanisms of antifungal resistance	4
Definitions of resistance	1	Conclusion and future directions	10
Detection of resistance in vitro	2	References	10
Correlation between in vitro and clinical resistance	4		

INTRODUCTION

The field of antifungal therapy is now enjoying its most dynamic era. The increased interest in antifungal agents is attributable to several factors. First, the fungi, which were once known only as the common causes of superficial infections, now have a well-established role in opportunistic invasive infections. The increase in the incidence of invasive mycoses originates from the increase in the number of patients who are at high risk of developing these infections. The use of more intensive chemotherapeutic regimens in patients with cancer, the appearance of acquired immunodeficiency syndrome (AIDS), and the increasing practice of organ and bone marrow transplantation all resulted in emergence of a particular host population who are highly immunocompromised and predisposed to develop invasive mycoses. The most significant aspects of these infections are that they are difficult to treat and associated with high rates of mortality (Anaissie 1992; McNeil et al. 2001; Kullberg and Lashof 2002). Second, more efficacious and less toxic antifungal agents appeared in clinical practice. Novel compounds with distinctive modes of antifungal activity and novel derivatives of the currently available agents were developed. As a consequence, we now have a diverse spectrum of antifungal agents in contrast to the limited number of such compounds available in the past (Table 1) (Arikan and Rex 2001, 2002). Third, due both to the increase in invasive infections and the related more common use of antifungal therapy, resistance to antifungal agents has become an issue, with both intrinsic (primary) and acquired (secondary) resistance being realized (Alexander and Perfect 1997; Bille 2000; Canuto and Rodero 2002; Sanglard and Odds 2002).

This chapter reviews:

- the definitions of resistance
- methods for in vitro antifungal susceptibility testing
- the correlation between in vitro resistance and clinical response in fungal infections
- the modes of action and mechanisms of resistance for currently available and novel antifungal drugs.

DEFINITIONS OF RESISTANCE

Meaning of resistance

Resistance, by definition, denotes the absence of activity of a drug against a particular microorganism. However, due to the multifactorial feature of the issue, the term is imprecise when used alone. It is important to distinguish in vitro, molecular, and clinical resistance (White et al. 1998). In vitro resistance is a minimum inhibitory concentration (MIC) value (μg/ml) of a drug against a particular strain that is above a predefined limit for that drug. Molecular resistance, on the other hand, is demonstration of resistance at genetic level and may include detection of point mutations, gene conversions, gene amplifications leading to overexpression, or mitotic recombinations. The best way to explore molecular mechanisms of resistance is to use matched sets of susceptible and resistant clinical isolates from the same strain. Clinical resistance is the ultimate issue and means

Table 1 *Classification of antifungal agents according to their chemical structure and modes of action*

Chemical structure	Antifungal agent(s)	Mode of action
Allylamines	Terbinafine, naftifine, butenafine	Inhibition of ergosterol synthesis
Azoles	Imidazoles: ketoconazole, clotrimazole, econazole, miconazole, oxiconazole, sulconazole Trizoles: fluconazole, itraconazole, voriconazole, posaconazole, ravuconazole	Inhibition of ergosterol synthesis
Echinocandins	Caspofungin, anidulafungin, micafungin	Inhibition of glucan synthesis
Fluorinated pyrimidine	Flucytosine	Nucleic acid inhibitor
Morpholine	Amorolfine	Inhibition of ergosterol synthesis
Peptide-nucleoside	Nikkomycin	Inhibition of chitin synthesis
Polyenes	Amphotericin B Lipid amphotericin B formulations Amphotericin B lipid complex (ABLC) Amphotericin B colloidal dispersion (ABCD) Liposomal amphotericin B (L-AMB) Nystatin Liposomal nystatin Pimaricin Filipin	Disruption of fungal cytoplasmic membrane
Tetrahydrofuran derivatives	Sordarins Azasordarins	Inhibition of fungal protein synthesis
Other	Griseofulvin	Antimitotic activity (spindle disruption)

clinical failure in response to treatment with an antifungal agent. The most striking point is that detection of resistance in vitro does not always mean clinical resistance. This follows from the multifactorial nature of the clinical response. Not only the in vitro activity of the drug but also its pharmacokinetic and pharmacodynamic properties, the immune status of the host, virulence factors of the infecting fungus, and existence of indwelling catheters determine the ultimate clinical outcome (Ghannoum and Rice 1999; Rex and Pfaller 2002). The major topic of interest is, of course, clinical resistance and we use in vitro susceptibility tests and molecular methods in an effort to predict clinical response.

Origin of resistance

The sources for the emergence of resistant fungal strains are diverse. Primary (intrinsic) resistance denotes natural resistance of a particular genus or species. The most typical example for this type of resistance is the resistance of *Candida krusei* (Collin et al. 1999) and *Aspergillus* to fluconazole (Edlind et al. 2001). Secondary (acquired) resistance, on the other hand, is acquisition of resistance or selection of a resistant strain following the pressure of antifungal therapy. Secondary resistance may emerge in various ways. One of the commonly observed types of secondary resistance is replacement with a more resistant species. Fluconazole prophylaxis or therapy, for instance, may lead to selection of a fluconazole-resistant *Candida glabrata* (Collin et al. 1999) or *C. krusei* strain (Bignardi et al. 1991; Casanovas et al. 1992). Antifungal therapy may also result in replacement with a more resistant strain. For example, following prolonged fluconazole therapy, a previously fluconazole-susceptible strain of *Candida albicans* may become fluconazole-resistant (Revankar et al. 1996; Marr et al. 1997; Franz et al. 1999). Temporary (epigenetic) resistance is another type of secondary resistance. This mostly originates from transient gene expressions under the pressure of antifungal therapy. Such a strain quickly reverts to a susceptible phenotype once the drug pressure is eliminated (Calvet et al. 1997). Finally, a single strain may include a resistant subpopulation which may again be selected under the pressure of antifungal therapy. This entity originates from genomic instability within a single strain and is known as 'population bottleneck' (Schoofs et al. 1997; White et al. 1998). Beyond these forms of resistance, alterations in cell type, such as yeast–hypha transitions or phenotypic switches (Ha and White 1999), as well as existence of putative virulence factors (Fekete-Forgacs et al. 2000) may be associated with resistance or decreased susceptibility. However, related data are limited.

DETECTION OF RESISTANCE IN VITRO

In vitro antifungal susceptibility testing emerged as an area of very active research since the 1990s. The increase in the invasive fungal infections and availability of an increased number of antifungal agents than ever before led to a great demand for standardization of antifungal susceptibility testing methods. The first standardized procedure for *Candida* and *Cryptococcus neoformans* was proposed in 1992 as NCCLS M27-P, which was followed by M27-T in 1995, M27-A in 1997, and finally M27-A2 in 2002 (National Committee for

Clinical Laboratory Standards 2002b). This remarkable progress led to the development of a reference method for some filamentous fungi as well; the NCCLS M38-P document was published in 1998 for testing *Aspergillus*, *Fusarium*, *Rhizopus*, *Pseudallescheria*, and mycelial phase of *Sporothrix schenckii*. The M38-P document has also been revised recently and the M38-A document is now also available (National Committee for Clinical Laboratory Standards 2002a). These testing procedures are based on a microdilution format procedure and have proven valuable in many settings. Some uncertainties still remain and clinical data are required for clarification of some in vitro findings. Some modifications of the reference microdilution method and assays other than microdilution (e.g. disk diffusion, Etest, and flow cytometry) have also been investigated and appear useful (Ramani and Chaturvedi 2000; Cuenca-Estrella and Rodriguez-Tudela 2001; Rex et al. 2001; Vandenbossche et al. 2002). Nevertheless, the reference microdilution method remains as the standard procedure and in vitro–in vivo correlation studies are mostly based on microdilution data.

The challenges for the reference method in terms of detection of resistance

Despite its being a great step in the field of mycology, the reference susceptibility testing method still provides only limited data. For yeasts, the MIC breakpoints to be used in detection of resistant isolates have as yet been defined only for fluconazole, itraconazole, and flucytosine and only against *Candida* (Table 2). For molds, an MIC breakpoint was proposed for detection of itraconazole resistance in *Aspergillus* (>8 μg/ml) (Espinel-Ingroff et al. 2001). The situation is also quite limited for amphotericin B against both yeasts and molds. The method frequently fails to detect amphotericin B-resistant isolates. Although some modifications of the reference method [antibiotic medium 3 instead of RPMI 1640 medium (Rex et al. 1995; Lozano-Chiu et al. 1998a, b); Etest instead of microdilution (Wanger et al. 1995)] have led to easier discrimination of the resistant isolates in some investigators' hands, work by others has failed to support the finding, particularly about the use of antibiotic medium 3 (Nguyen et al. 1998) and significant variability is the rule rather than the exception (Lozano-Chiu et al. 1997). Detection of unusually high MICs, however, may suggest putative resistance for any fungus–drug combination with undefined MIC breakpoints.

Resistant fungi

The overall data obtained by the reference method suggest that resistance is more likely for particular fungal genera or species against specific antifungal agents. This finding emphasizes the significance of identification of a fungal isolate to species level. The fungi which have been observed to display significant rates of antifungal resistance are summarized in Table 3. For some of these, resistance is primary and includes all strains classified in that genus (e.g. fluconazole resistance in *C. krusei*). For others, resistance is detected at variable rates for the strains of a species. Apart from those noted in Table 3, strain-to-strain variations in antifungal susceptibility profiles are always possible even for a genus known to be susceptible to an antifungal agent. The typical example for this entity is *C. albicans*, a species well known to be susceptible to azoles. As noted previously, fluconazole resistance may develop in a previously susceptible *C. albicans* strain following antifungal prophylaxis or therapy with fluconazole (Marr et al. 1997).

Another topic that merits discussion under this heading is cross-resistance. Cross-resistance is now more significant than ever before due to the availability of novel derivatives of the azoles. Does, for instance, a fluconazole-resistant *C. glabrata* isolate remain resistant to itraconazole or voriconazole as well? Available data suggest that cross-resistance between old and novel azoles is likely but not universal (Cartledge et al. 1997; Nguyen and Yu 1998; Goldman et al. 2000; Muller et al. 2000; Mosquera and Denning 2002). The same is true for polyenes. Some amphotericin B-resistant *Candida* isolates remain susceptible to nystatin and liposomal nystatin (Arikan et al. 2002a). These data indicate that

Table 2 *MIC interpretive guidelines for susceptibility testing of* Candida *(National Committee for Clinical Laboratory Standards 2002b)*

Antifungal agent	Susceptible (S)	Susceptible-dose dependent (S-DD)	Intermediate (I)	Resistant (R)
Fluconazole[a]	⩽8	16-32[b]	–	⩾64
Itraconazole	⩽0.125	0.25-0.5[c]	–	⩾1
Flucytosine	⩽4	–	8-16[d]	⩾32

a) *C. krusei* is intrinsically resistant to fluconazole and these guidelines should not be used for assessment of fluconazole susceptibility of *C. krusei*.
b) Fluconazole doses of at least 400 mg/day may be required in adults with normal renal function to achieve adequate blood levels for treating infections due to these isolates.
c) Plasma itraconazole concentrations of >0.5 μg/ml may be required for optimal response in treating infections due to these isolates.
d) Isolates with uncertain susceptibility profile.

Table 3 *Fungal genera/species for which a significant incidence of resistance to antifungal agents has been observed*[a]

Fungus	Antifungal agent	Type of resistance	Reference(s)
Yeasts			
Candida glabrata	Azoles	Primary/secondary	Yamaguchi et al. (1989); Collin et al. (1999); Arikan et al. (2002b); Pfaller et al. (2002)
Candida guilliermondii	Amphotericin B	Primary	Dick et al. (1985); Collin et al. (1999); Krcmery and Barnes (2002)
Candida krusei	Azoles	Primary	Rex et al. (1998); Collin et al. (1999); Pfaller et al. (2001)
	Amphotericin B	Primary	Rex et al. (1998); Arikan et al. (2002a); Krcmery and Barnes (2002)
Candida lusitaniae	Amphotericin B	Primary/secondary	Pietrucha-Dilanchian et al. (2001); Arikan et al. (2002a); Ellis (2002); McClenny et al. (2002)
Cryptococcus neoformans	Flucytosine	Primary/secondary	Block et al. (1973); Brandt et al. (2001)
Trichosporon spp.	Amphotericin B	Primary	Walsh et al. (1990); Arikan and Hascelik (2002); Toriumi et al. (2002)
Molds			
Aspergillus spp.	Fluconazole	Primary	Abrahamsen et al. (1992); Edlind et al. (2001)
Aspergillus terreus	Amphotericin B	Primary	Lass-Florl et al. (1998); Sutton et al. (1999)
Fusarium solani	Amphotericin B	Primary	Anaissie et al. (1992); Arikan et al. (1999); Ellis (2002)
Scedosporium apiospermum	Amphotericin B	Primary	Walsh et al. (1995); Espinel-Ingroff (1998); Ellis (2002)
Scedosporium prolificans	Amphotericin B	Primary	Berenguer et al. (1997); Maertens et al. (2000); Ellis (2002)

a) This table covers the fungi that are relatively commonly reported to be resistant to antifungal agents. Fungi for which resistance was detected less frequently and/or in a few strains were not included. It should be remembered that strain-to-strain variations in susceptibility are possible.

class-based in vitro susceptibility tests are not adequate for definitive determination of the susceptibility profile of an isolate.

CORRELATION BETWEEN IN VITRO AND CLINICAL RESISTANCE

A recent meta-analysis of the available in vitro–in vivo correlation studies found that the percentage of clinical success was 91 percent for infections due to isolates susceptible to the corresponding antifungal agent while it was 48 percent for those where the isolate were resistant (Rex and Pfaller 2002). These success rates were shown to be similar to the success rates for therapy of susceptible/resistant bacterial isolates, and the general concept of a 90/60 rule was proposed in which susceptible isolates responded about 90 percent of the time and resistant isolates responded about 60 percent of the time. This analysis makes it clear that in vitro susceptibility tests can predict clinical resistance. However, several other factors, such as the immune status of the host and severity of the infection in the interim, influence the clinical outcome and should be considered.

Noteworthy, in vitro–in vivo correlation studies for amphotericin B are not included in this meta-analysis. Available data are limited and remain ambiguous in this respect. Although a correlation between in vitro and clinical resistance could be demonstrated in some *Candida* (Nguyen et al. 1998) and *Aspergillus* (Lass-Florl et al. 1998) infections by using a proposed MIC breakpoint value, further data to support these findings, unfortunately, are not available.

MECHANISMS OF ANTIFUNGAL RESISTANCE

The cellular and molecular bases of resistance are tightly related to the modes of antifungal activity. The modes of action of currently available and novel antifungal agents are summarized in Table 1.

Polyenes

This group of antifungal agents includes amphotericin B, nystatin, lipid formulations of amphotericin B and nystatin, pimaricin, and filipin (Table 1). The most significant agent in terms of clinical implications of resistance is amphotericin B and most of our knowledge about polyene resistance is provided by clinical and investigational data for amphotericin B.

Amphotericin B has been in clinical use since the 1960s and remains a mainstay of systemic antifungal therapy. The use of amphotericin B was further augmented by the development of its lipid formulations [amphotericin B lipid complex (ABLC), amphotericin B

colloidal dispersion (ABCD), and liposomal amphotericin B (L-AMB)] in the 1990s. These lipid formulations are at least as efficacious as the parent drug and definitely less nephrotoxic than the conventional formulation, amphotericin B deoxycholate. Their acquisition cost, however, is remarkably high (Arikan and Rex 2001, 2002).

As noted previously, the major challenge with in vitro amphotericin B susceptibility testing is the frequent inability of the reference method in detection of resistant isolates. Unusually high MICs of amphotericin B have been remarkable for isolates of *Candida guilliermondii*, *C. krusei*, *Candida lusitaniae*, *Trichosporon* spp., *Aspergillus terreus*, *Scedosporium apiospermum*, *Scedosporium prolificans*, and *Fusarium solani* (Table 3). Although some differences have been detected between the in vitro activity of amphotericin B deoxycholate and its lipid formulations (Pahls and Schaffner 1994; Carrillo-Munoz et al. 1999; Oakley et al. 1999), based on the fact that the compound responsible for the antifungal activity is identical in all formulations, most authorities suggest that testing the in vitro activity of lipid formulations is not required. Importantly, in vivo resistance to amphotericin B is not common and, when present, usually originates from the impaired immune status of the host. Development of secondary resistance to amphotericin B is also not a major problem, despite its being in clinical use for more than 40 years. This is probably due to the fungicidal nature of the agent.

The antifungal activity of amphotericin B and other polyenes is via a specific interaction between the agent and ergosterol, the bulk sterol found in fungal cell membrane. Ergosterol is an essential element to maintain fluidity and integrity of the membrane and proper functioning of the membrane-bound enzymes. Amphotericin B intercalates into the membrane and generates channels and pores. Through these pores, several cellular components, particularly potassium and magnesium ions, leak and destroy the proton gradient within the membrane, leading to death of the fungal cell (Vanden Bossche et al. 1994a; Ellis 2002). In addition, it has previously been reported that amphotericin B may be cytotoxic to *Candida* via its prooxidative activity (Sokol-Anderson et al. 1986). However, and contrary to this finding, more recent data suggest that amphotericin B may act as an antioxidant (Osaka et al. 1997) and this question remains unresolved. The affinity of amphotericin B is high for ergosterol and less for 3-hydroxy or 3-oxo sterols. This low affinity for sterols such as fecosterol and episterol may be significant in emergence of resistance to amphotericin B (Ghannoum and Rice 1999).

Any quantitative or qualitative change in sterol content of the fungal cell influencing the amount or the availability of ergosterol may result in resistance to amphotericin B (Table 4). The three mechanisms of quantitative ergosterol changes are decrease in amount of ergosterol due to inhibition of its synthesis (Merz and Sanford 1979; Dick et al. 1980; Peyron et al. 2002), replacement of ergosterol with episterol, fecosterol or other sterols (Woods et al. 1974; Kelly et al. 1994; Peyron et al. 2002), and alterations in the ratio of sterols to phospholipids. A fourth mechanism that may lead to resistance is a qualitative change in ergosterol; its reorientation or masking in the membrane. This in turn results in sterically or thermodynamically less favored binding with amphotericin B (Ghannoum and Rice 1999). A fifth mechanism related to amphotericin B resistance is related to the growth phase of the fungal cell. As expected, during exponential growth, breakdown and resynthesis of the cell wall occurs at a high rate, providing enhanced access of amphotericin B to the cell membrane. By contrast, at stationary growth phase, breakdown and synthesis of the cell wall occurs at a much lower rate, leading to relative resistance to amphotericin B (Gale et al. 1975).

Table 4 *Possible mechanisms of amphotericin B resistance*

Mechanism
Reduced ergosterol content of the fungal cytoplasmic membrane (defective *ERG2* or *ERG3* genes)
Alterations in sterol content of the membrane (predominancy of sterols with reduced affinity, such as fecosterol and episterol)
Alterations in sterol to phospholipid ratio in the membrane
Reorientation or masking of ergosterol in the membrane
Stationary growth phase of the fungus
Increase in the levels of alkali-soluble and -insoluble glucans in the cell wall
Production of melanin
Previous exposure to azoles

There are two newly proposed mechanisms associated with amphotericin B resistance. The first is related to the cell wall. Alterations in the cell wall components of mycelia, specifically an increase in the levels of alkali-soluble and insoluble glucans, have been postulated to lead to amphotericin B resistance in *Aspergillus flavus* (Seo et al. 1999). The second is related to the production of melanin. Killing assays demonstrated that melanized isolates of *Cryptococcus neoformans* and *Histoplasma capsulatum* were less susceptible to amphotericin B compared to the nonmelanized strains. Of interest, the reference M27-A method failed to detect this melanin-associated difference in amphotericin B susceptibility (van Duin et al. 2002).

Previous exposure to an azole compound may also be responsible for amphotericin B resistance. The key issue here is the depletion of ergosterol, the target molecule of amphotericin B, by the previous antifungal activity of the azole. This kind of interaction of an azole with amphotericin B is one of the major examples for antag-

onism of the action of one antifungal by that of another (Schaffner and Böhler 1993; Martin et al. 1994; Sugar and Liu 1998). However, the related clinical implications are complex and the details are beyond the scope of this chapter.

MOLECULAR ASPECTS OF AMPHOTERICIN B RESISTANCE

Only a few studies have focused on the genetic basis of amphotericin B resistance in clinical isolates. Several enzymes take part in the chain of reactions starting from squalene and ending up with synthesis of ergosterol. In this ergosterol synthesis pathway, the mutations in two genes encoding two enzymes have been found to be associated with amphotericin B resistance. C-8 sterol isomerase catalyzes the production of episterol from fecosterol and is regulated by the *ERG2* gene. C-5 sterol desaturase, on the other hand, is one of the enzymes in conversion of episterol to ergosterol and is encoded by the *ERG3* gene. Clinical strains of amphotericin B-resistant *C. albicans* with reduced ergosterol content and defective *ERG2* or *ERG3* genes have been reported (Broughton et al. 1991; Haynes et al. 1996; Nolte et al. 1997). The stability of these mutations remains unknown. Sterol analysis of an amphotericin B-resistant mutant isolate of *C. neoformans* has also suggested an alteration in the *ERG2* gene (Kelly et al. 1994).

Azoles

This group of antifungal agents includes imidazoles and triazoles (Table 1). Fluconazole is the most widely used azole compound. Its favorable clinical efficacy and safety, as well its availability in both oral and parenteral formulations, led to widespread use of fluconazole for both treatment and prophylaxis. With such broad usage, it is perhaps not surprising that fluconazole-resistant isolates were soon noted and this led to efforts to develop novel compounds with favorable activity against fluconazole-resistant organisms.

The antifungal activity of the azoles is via inhibition of lanosterol (14-alpha) demethylase, an enzyme which functions in synthesis of ergosterol from lanosterol (Sanati et al. 1997). There are data suggesting that the azoles primarily target the heme protein which cocatalyzes cytochrome P450-dependent 14-alpha-demethylation of lanosterol (Hitchcock et al. 1990). The inhibition of demethylation results in depletion of ergosterol and accumulation of 14-alpha-methylated sterols such as lanosterol, 4,14-dimethylzymosterol, and 24-methylene-dihydrolanosterol. Finally, the integrity of the membrane and its functions, such as nutrient transport and chitin synthesis, are lost, leading to inhibition of fungal growth. The mechanism of antifungal activity may vary depending on the genus of the fungus. For example, fluconazole and itraconazole affect the reduction of obtusifolione to obtusifoliol as well as inhibiting 14-alpha-demethylase in *C. neoformans* and both mechanisms result in accumulation of methylated sterol precursors (Vanden Bossche et al. 1993; Ghannoum et al. 1994).

The clinical effect of inhibition of sterol biosynthesis on human enzymes merits discussion. This adverse effect is mostly observed for ketoconazole. Azoles block the synthesis of mammalian cholesterol as well at the stage of 14-alpha demethylation. However, it has been demonstrated by Hitchcock et al. (1995) that the 50 percent inhibitory concentration of voriconazole needed to inhibit 14-alpha-demethylase of rat liver cholesterol is much higher than that required to inhibit fungal demethylase (7.4 μM versus 0.03 μM).

As shown in Table 5, azole resistance may originate from qualitative or quantitative changes in the target enzyme lanosterol demethylase, reduction in the intercellular concentration of the drug or a combination of these mechanisms (Lupetti et al. 2002; Sanglard and Odds 2002). Qualitative alterations in the enzyme frequently originate from the mutations in the encoding gene and result in reduced binding affinity of the enzyme for azoles. Interestingly, species-dependent intrinsic qualitative differences may also be observed. Compared to that of *C. albicans*, lanosterol demethylase of *C. krusei* displays reduced susceptibility to inhibition by fluconazole (Orozco et al. 1998). Quantitative modifications, on the other hand, are due to increased copy number of the enzyme and lead to increased ergosterol synthesis due to its overexpression. Azole resistance may sometimes develop due to its unfavorably low intercellular concentration. This may be observed for two reasons. First, the azole may penetrate poorly across the membrane due to the alterations in sterol and/or phospholipid composition of the membrane and related reduced permeability. Second, and more importantly, the azole can readily get access to its target initially but is then pumped out by overexpressed efflux systems (Ghannoum and Rice 1999). There are no reports suggesting the relevance of modification of azoles as a mechanism of resistance.

Table 5 *Possible mechanisms of azole resistance*

Mechanism
Alteration in lanosterol demethylase
Overexpression of lanosterol demethylase
Reduction in intercellular concentration of the azole
1 Overexpression of energy-dependent efflux systems
i ATP-binding cassette (ABC) superfamily proteins
ii Major facilitator superfamily proteins
2 Changes in sterol and/or phospholipid composition of fungal cell membrane leading to decreased permeability

MOLECULAR ASPECTS OF AZOLE RESISTANCE

Lanosterol demethylase is encoded by the *ERG11* gene and the active site pocket of the enzyme is located on top of the heme cofactor. This gene has previously been referred to as *ERG16* and *CYP51A1* in *C. albicans*. Various genetic alterations in *ERG11*, including point mutations, overexpression, gene amplification leading to overexpression, gene conversion, and mitotic recombination have been observed in *C. albicans* (White et al. 1998) and appear related to azole resistance. In addition, alterations in other *ERG* genes encoding enzymes that function in ergosterol biosynthetic pathway may also be associated with azole resistance. Among these are *ERG3* (Kelly et al. 1997) and *ERG5* (White et al. 1998).

Point mutations in *ERG11*

Point mutations in *ERG11* associated with azole resistance have been reported. While some of them have been identified in clinical isolates, others were developed in laboratory strains. Seven different point mutations associated with azole resistance have so far been defined. However, since matched sets of susceptible and resistant isolates from the same strain have not been tested, it is hard to know whether these mutations are the actual causes of resistance (Loeffler et al. 1997). Moreover, recent data suggest that the resistance mechanisms identified in matched sets of susceptible and resistant isolates frequently remain insufficient to explain resistance in unmatched clinical isolates (White et al. 2002). A point mutation leading to replacement of arginine with lysine at amino acid 467 (abbreviated as *R467K*) has been found to be associated with azole resistance in a clinical strain of *C. albicans* when matched strains were tested (White 1997b). Another point mutation was constructed in the laboratory in a *C. albicans* strain, leading to the replacement of threonine with alanine at position 315 (*T315A*) and this mutation has also been studied in *Saccharomyces cerevisiae*. Importantly, the *T315A* mutation was located in the active site pocket of the enzyme and led to reduction in azole binding and fluconazole resistance (Lamb et al. 1997). *D116E* and *E266D* are the other two of the most common point mutations in *ERG11* of *C. albicans*. However, these mutations are frequently observed and are not necessarily associated with resistance (White et al. 2002). Geber et al. (1995) demonstrated that the *ERG11* deletion mutant of *C. glabrata* was resistant to fluconazole (at 100 μg/ml) and itraconazole (at 16 μg/ml) as well as amphotericin B (at 2 μg/ml).

Overexpression of *ERG11*

Although overexpression of the *ERG11* gene has been shown in clinical isolates of *C. albicans* resistant to azoles, the contribution of this phenomenon alone to development of resistance remains unknown (Sanglard et al. 1995; Albertson et al. 1996; White 1997a; Sanglard et al. 1998). Other alterations, such as the *R467K* mutation and the overexpression of the genes encoding efflux pump systems, have always been present in the resistant isolates with an overexpressed *ERG11* gene. Importantly, recent data from a collection of unmatched clinical isolates of *C. albicans* suggest that overexpression of *ERG11* is not correlated with azole resistance (White et al. 2002). Overexpression of *ERG11* may originate from an increase in the number of gene copies and *ERG11* gene amplification is another postulated mechanism for azole resistance. In a clinical isolate of resistant *C. glabrata*, *ERG11* gene amplification, increase in *ERG11* mRNA levels, and an associated increase in lanosterol demethylase have been detected. The gene amplification observed in this isolate was linked to a chromosome duplication. In the same isolate, increased drug efflux and change in *ERG7* activity was also present (Vanden Bossche et al. 1992, 1994a, b; Marichal et al. 1997). Overexpression of *ERG11* in *C. albicans*, however, could not be linked to *ERG11* amplification by some authorities (Sanglard et al. 1995; White 1997a).

Efflux pumps

There are two types of efflux pumps that contribute to azole resistance; ATP binding cassette (ABC) transporters and major facilitator superfamily (MFS) proteins. The ABC system uses ATP as the energy source while the MFS proteins use proton motive force of the membrane (the H^+ gradient across the membrane). Efflux pump systems have been found to be associated with fluconazole and itraconazole resistance in *C. krusei* (Marichal et al. 1995; Venkateswarlu et al. 1996) and *C. glabrata* (Sanglard et al. 1999), itraconazole resistance in *Aspergillus fumigatus* (Denning et al. 1997), and secondary fluconazole resistance in *C. albicans* (Marr et al. 1997).

The ABC transporters are encoded by several genes. The major ABC genes proven to be correlated with azole resistance are the *CDR* genes. *CDR* genes appear to function in efflux of various azoles. Overexpression of *CDR1* (Sanglard et al. 1995; White 1997a; Maebashi et al. 2001; White et al. 2002) and *CDR2* (Maebashi et al. 2001; White et al. 2002) have been correlated with azole resistance in *C. albicans* strains. Similar to the data demonstrated for *C. albicans*, the *CgCDR1* gene was found to be involved in azole resistance in *C. glabrata* (Sanglard et al. 1999). The *ABC1* gene, on the other hand, appears to be potentially involved in azole resistance of *C. krusei* (Katiyar and Edlind 2001).

The data concerning the genetic regulation of MFS proteins are more limited than those for the ABC system. *MDR1* (*BEN-R*) is the major MFS gene cloned from *C. albicans* and appears to be specific for fluconazole. Current data suggest a correlation between *MDR1*

overexpression and azole resistance in *C. albicans* (Sanglard et al. 1995; Albertson et al. 1996; White 1997a) and *C. dublininensis* (Wirsching et al. 2001). No correlation could be found between overexpression of *FLU1*, which is an efflux pump gene related to *MDR1*, and azole resistance (White et al. 2002).

The overexpression of *CDR* and *MDR1* genes has so far been demonstrated by the increase in their mRNA levels. Increased mRNA levels of CDR were found to be associated with development of rapid, transient fluconazole resistance in *C. albicans* (Marr et al. 1998). The definitive causes of the increase in mRNA levels, however, remain yet unknown (Lyons and White 2000). It may result from gene amplification, increased transcription from endogenous copies of the gene, or increase in half-life of mRNA and its slower degradation (Borst 1991).

Decreased membrane permeability

Changes in sterol and/or phospholipid composition of the fungal cell membrane have been postulated by some investigators to lead to decreased membrane permeability and a reduction in the amount of the drug taken up by the fungal cell. The most significant alteration in sterol composition was found to be the depletion of ergosterol and its replacement with methlyfecosterol and other methylated sterols in *C. albicans* (Kohli et al. 2002). However, other workers reported that no correlation between the sterol composition and azole resistance could be demonstrated in *C. albicans* (Ghannoum and Rice 1999). A recent study by Kohli et al. (2002) demonstrated that changes in status of the membrane lipid phase, asymmetrical distribution of phosphatidylethanolamine and its increased exposition to the outer monolayer could contribute to azole resistance in *C. albicans*.

Cross-resistance in azoles

CDR overexpression and the *R467K* point mutation in *ERG11* appear to be associated with azole cross-resistance. Due to its specificity for fluconazole, *MDR1* overexpression does not lead to cross-resistance to other azoles (Sanglard et al. 1995, 1996). Whether other point mutations and mechanisms result in cross-resistance awaits further analysis.

Current status

Azole resistance is a gradual process and involves several alterations, particularly in strains under continuous antifungal drug pressure (Marr et al. 1997; Franz et al. 1998; Lopez-Ribot et al. 1998). The data obtained by analysis of ergosterol biosynthetic pathway in a particular genus or species may not be relevant to others, including the closely related ones. The contribution of some mechanisms alone remains unknown and available data suggest that further mechanisms may have a significant role in development of resistance. One of the novel mechanisms reported to be associated with fluconazole resistance in *C. albicans* is sequestration of fluconazole in vesicular vacuoles (Maebashi et al. 2002). Importantly, simultaneous contribution of several mechanisms to fluconazole resistance in *C. albicans* strains was verified by Perea et al. (2001). In this study, overexpression of efflux pump genes, amino acid substitutions in lanosterol demethylase due to mutations in *ERG11*genes, and overexpression of *ERG11* were detected in 85, 65, and 35 percent, respectively. Overall, multiple mechanisms of resistance were found to be active in 75 percent of the studied isolates.

Allylamines

This group of antifungal agents (Table 1) yield antifungal activity via inhibition of squalene epoxidase enzyme (encoded by the *ERG1* gene) which converts squalene to 2,3-oxidosqualene in the ergosterol biosynthetic pathway. This in turn leads to accumulation of squalene and a resulting increase in membrane permeability and disruption of cellular organization. Terbinafine is the most commonly used allylamine derivative in clinical practice. While it has proven to be efficacious in cutaneous mycoses, subcutaneous mycoses (including sporotrichosis, chromoblastomycosis, and maduromycosis), refractory and disseminated aspergillosis, infections due to some azole-resistant *Candida* strains, pheohyphomycosis, and cutaneous leishmaniasis (Ghannoum and Elewski 1999; Perez 1999), dermatophytosis is the most common clinical indication for terbinafine use (Gupta and Shear 1997).

Cases of onychomycosis that failed to respond to terbinafine have been seen particularly with *Trichophyton rubrum* infection. However, in vitro susceptibility data suggested that clinical failure in these cases was not due to development of resistance to terbinafine and host-related factors might have contributed (Bradley et al. 1999). More recently, primary resistance to terbinafine was observed in a clinical isolate of *T. rubrum* from a patient with onychomycosis, suggesting that terbinafine-resistant dermatophytes are rare, but do exist (Leidich et al. 2001).

MOLECULAR ASPECTS OF ALLYLAMINE RESISTANCE

Due to the very rare detection of terbinafine-resistant dermatophytes, no data are available on genetic analysis of terbinafine resistance in this particular group of fungi. However, parallel data for other fungal genera suggest that efflux pumps may play a role in terbinafine resistance. Vanden Bossche et al. (1998) reported that overexpression of *MDR1* may be related to resistance to fluconazole and terbinafine while that of *CDR1* may lead to cross-resistance to fluconazole, itraconazole,

ketoconazole, and terbinafine in *S. cerevisiae*. Also, *ERG* upregulation, particularly of *ERG11*, has been observed in vitro following treatment of *C. albicans* cultures with azoles and terbinafine (Henry et al. 2000).

Flucytosine

Flucytosine (5-fluorocytosine) is a fluorinated pyrimidine that exerts antifungal activity via inhibition of nucleic acid and protein synthesis. Flucytosine is taken up into the cell by fungal cytosine permease and then is deaminated to 5-fluorouracil (5-FU) via action of cytosine deaminase. 5-FU is initially converted to 5-fluorodeoxyuridine monophosphate and 5-fluorouridylic acid. The latter reaction is catalyzed by uracil phosphoribosyltransferase (UPRTase). Further phosphorylation results in production of 5-fluorouracil triphosphate (5-FUTP). There are two key metabolites of flucytosine that provide antifungal activity. The first, 5-fluorodeoxyuridine monophosphate, inhibits DNA synthesis via inhibition of thymidylate synthase. The second, 5-FUTP, is incorporated into RNA and disrupts protein synthesis (Polak 1977).

Flucytosine is primarily indicated for treatment of cryptococcal meningitis in combination with amphotericin B and/or fluconazole due to its favorable interaction with amphotericin B in this particular setting (Dismukes et al. 1987; Rodero et al. 2000). Primary resistance to flucytosine has been reported in *C. albicans*, non-*albicans Candida*, *C. neoformans*, and *Aspergillus*, while secondary resistance has been observed in *C. albicans* and *C. neoformans* (Vanden Bossche et al. 1994b, 1998; Barchiesi et al. 2000; Cuenca-Estrella et al. 2001). The key precaution to prevent development of secondary resistance to flucytosine is to avoid flucytosine monotherapy (Vermes et al. 2000). Resistance to flucytosine may develop due to loss of permease activity, a defect in cytosine deaminase activity or decrease in the activity of UPRTase enzyme. The defect in cytosine deaminase usually results in primary resistance, while a decrease in UPRTase activity leads to secondary resistance in *C. albicans* and *C. neoformans* (Whelan 1987; Vanden Bossche et al. 1994b). Loss of permease activity, on the other hand, has been found to be associated with flucytosine resistance in *C. glabrata* and *S. cerevisiae*, but does not seem to be significant in *C. albicans* and *C. neoformans* (Jund and Lacroute 1970; Whelan 1987).

MOLECULAR ASPECTS OF FLUCYTOSINE RESISTANCE

Genetic basis of flucytosine resistance has been explored in several fungi, particularly in *C. albicans* and *C. neoformans*. Two resistance genes, *FCY1* and *FCY2*, have been defined for flucytosine (Alexander and Perfect 1997). Since the fungus is diploid, it has two alleles for each gene and the sequential differences between the two alleles lead to *FCY* homozygotes and heterozygotes. Accordingly, a strain may be homozygous sensitive (*FCY*/*FCY*), homozygous resistant (*fcy*/*fcy*), or heterozygous (*fcy*/*FCY*). The heterozygotes are slightly resistant to flucytosine but they occur at significantly high ratio. Also, they carry preexisting resistance determinants which may lead to clinical treatment failures following development of homozygosity. Resistance in *fcy1*/*fcy1* strains was found to be associated with decreased UPRTase activity, whereas resistance in *fcy2*/*fcy2* strains was associated with decreased cytosine deaminase activity (Whelan 1987).

Echinocandins

Echinocandins (Table 1) are lipopeptides which exert antifungal activity via noncompetitive inhibition of synthesis of 1,3-beta-D-glucan, the essential cell wall homopolysaccharide in several pathogenic fungi. Glucan synthase is a heteromeric enzyme complex composed of two subunits; the large integral membrane protein referred to as FKS1 or FKS2 (encoded by *FKS1* and *FKS2* genes which are highly homologous), and the small subunit more loosely associated with the membrane and referred to as *RHO1*. *FKS1p* constitutes the majority of the activity in vegetatively growing cells while the *FKS2* gene product is required for sporulation. Although some investigators have postulated that inhibition of glucan synthesis by echinocandins is via inhibition of glucan synthase enzyme, definitive evidence to support this theory is lacking. According to these authorities, echinocandins affect the function of the Fksp component from either *FKS* gene (Kurtz and Douglas 1997).

Echinocandins are active against *Candida* and *Aspergillus* spp. Based on their distinct mode of action, activity of echinocandins against azole-resistant strains is one of their most significant features (Cuenca-Estrella et al. 2000). Caspofungin is as yet the only licensed novel echinocandin in the USA and is indicated for salvage therapy in refractory invasive aspergillosis (Groll and Walsh 2001). *C. neoformans* and *Fusarium* spp. are intrinsically resistant to echinocandins. The data obtained by Feldmesser et al. (2000) suggest that the limited action of the echinocandins against *C. neoformans* may originate from their reduced activity against glucan synthase of this particular organism or from yet undefined mechanisms. Interestingly, the production of melanin has recently been demonstrated to lead to reduced susceptibility to caspofungin in *C. neoformans* and *H. capsulatum* (van Duin et al. 2002). Echinocandin-resistant mutants of *S. cerevisiae* and *C. albicans* have been studied. The results obtained by Kurtz et al. (1996) suggested that these mutants may have alterations in glucan synthase activity. The use of caspofungin has been limited to date and reports of secondary resistance are not available.

MOLECULAR ASPECTS OF ECHINOCANDIN RESISTANCE

Although genetic studies in *S. cerevisiae* have shown that mutations in the *FKS1* and *FKS2* genes result in caspofungin resistance, no data have been available about the influence of gene overexpression on caspofungin resistance. *FKS1* mutations conferred high-level resistance to echinocandins. Mutations in another cell wall synthesis gene, *GNS1* (encodes an enzyme that functions in fatty acid elongation), on the other hand, were shown to result in low level resistance (Kurtz and Douglas 1997). In addition and recently, a novel mechanism of echinocandin resistance has been proposed. Osherov et al. (2002) demonstrated that overexpression of Sbe2p (encodes a Golgi protein involved in the transport of cell wall components) under the regulated control of the *GAL1* promoter results in caspofungin resistance in *S. cerevisiae*.

Griseofulvin

Griseofulvin has remained a first-line drug for treatment of dermatophytosis for may years. However, following the emergence of more effective and less toxic alternatives, itaconazole and terbinafine, the clinical use of griseofulvin is now limited (Zaias et al. 1996). Griseofulvin exerts antifungal activity via inhibition of fungal mitosis by disrupting the mitotic spindle through interaction with polymerized microtubules (Gull and Trinci 1973). Cases refractory to griseofulvin therapy have been reported (Lukacs et al. 1994). The clinical success rate in dermatophytic onychomycosis may be as low as 30 percent (Roberts 1994). The lack of a standardized method for susceptibility testing of dermatophytes and the absence of a defined griseofulvin MIC breakpoint limit our ability to estimate the rate of in vitro resistance to griseofulvin. Griseofulvin yielded higher MICs compared to terbinafine and itraconazole when tested against clinical *Trichophyton rubrum* isolates (Korting et al. 1995; Jessup et al. 2000) and was found to be less active than voriconazole against most dermatophytes (Wildfeuer et al. 1998). The in vitro activity of griseofulvin against *Trichophyton mentagrophytes* was less when compared to that against *T. rubrum* (Korting et al. 1995). Laboratory mutants resistant to griseofulvin have been observed following exposure to increasing gradients of the drug, mutagenic treatment or UV radiation (Aytoun et al. 1960; Iwata 1991; Fachin et al. 1996). Data on griseofulvin resistance are thus limited and the molecular basis of resistance mechanisms remains uncertain.

CONCLUSION AND FUTURE DIRECTIONS

Antifungal resistance is a complex, gradual, and multifactorial issue. Areas of significant uncertainty persist and molecular assays to detect antifungal resistance are not simple. Based on the dynamic interaction between the host, the infecting fungus, and the antifungal agent, antifungal resistance is not the only factor influencing clinical outcome. The immune status of the host plays a very important role in this regard. Proper dosing strategies and restricted and well-defined indications for antifungal prophylaxis appear as the future directions to avoid development of secondary resistance.

Management of superficial infections

JEFF WEEKS AND BONI ELEWSKI

Antifungal agents 1
Therapy of selected superficial infections 4
Conclusion 8
References 9

Successful treatment of superficial fungal infections requires knowledge of the various antifungal agents and familiarity with measures that can be taken to reduce the chance of spread or reinfection. There are multiple topical and systemic antifungal agents available to treat these infections. In order to choose the most effective medication, the clinician needs a basic understanding of the drugs available as well as their mechanisms of action, indications, dosages, interactions, and adverse effects. Many conditions, such as tinea corporis and tinea cruris, usually respond well to topical agents. Others, such as tinea capitis and onychomycosis, generally require systemic therapy. The newer systemic agents including fluconazole, itraconazole, and terbinafine offer greater efficacy, broader spectrums of activity and shortened treatment duration. However, they are not without potential adverse effects and drug interactions and their use requires careful patient selection and monitoring.

This chapter discusses the management of a variety of superficial cutaneous infections including:

- superficial mycoses
- dermatophytoses
- disease caused by nondermatophyte molds
- cutaneous candidiasis.

A summary of the topical and systemic pharmaceutical agents commonly used for these conditions is presented. This includes a discussion of the indications, dosages, mechanisms of action, drug interactions, and adverse effects of selected antimycotics. Also discussed are measures that should be taken to reduce the chance of spread or recurrence of the infection.

ANTIFUNGAL AGENTS

There are multiple topical and systemic antimycotics that are effective in the management of superficial fungal infections. The most widely used today fall into three main classes: the polyenes, azoles, and allylamines/benzylamine. Others that are not included in these classes include griseofulvin, ciclopirox, tolnaftate, and selenium sulfide.

Polyenes

The polyenes were the first specific antifungals (Phillips and Rosen 2001). Members of this group include topical/oral nystatin and topical/intravenous (IV) amphotericin B (see Table 1). Although nystatin can be orally dosed, it is not absorbed. The polyenes bind fungal cell wall sterols, thus altering membrane permeability and allowing leakage of intracellular contents. Both agents are active against *Candida* species when topically applied but are ineffective against dermatophytes. Although still available from the manufacturer upon special request, topical amphotericin is rarely used today (Phillips and Rosen 2001). The usage of IV amphotericin is generally limited to systemic mycoses, and is beyond the scope of this chapter.

Azoles

The azole family can be subdivided into the topical/oral imidazoles (see Table 1) and the newer oral/IV triazoles (fluconazole, itraconazole, and voriconazole). Compared to the polyenes, both subsets have extended

Table 1 *Selected topical antifungals*

Class	MOA	Active against	Dosing frequency
Polyenes			
Nystatin	Bind to fungal cell wall sterols, increasing permeability	*Candida*	b.i.d.–t.i.d.
Amphotericin B			b.i.d.–q.i.d.
Imidazoles			
Clotrimazole	Block lanosterol 14α-methylase thus inhibiting fungal cell wall ergosterol synthesis	*Candida*, dermatophytes, *Malassezia*; econazole has some antibacterial activity	b.i.d.
Econazole			q.d.–b.i.d.
Ketoconazole			q.d.–b.i.d.
Miconazole			b.i.d.
Oxiconazole			q.d.–b.i.d.
Sulconazole			q.d.–b.i.d.
Allylamines			
Butenafine	Inhibit squalene epoxidase thus inhibiting fungal cell wall ergosterol synthesis. Squalene accumulation within cell is toxic	*Candida*, dermatophytes	q.d.
Naftifine			q.d.
Terbinafine			q.d.–b.i.d.
Substituted pyridone			
Ciclopirox	Alters active membrane transport, cell membrane integrity and cell respiratory processes	*Candida*, dermatophytes, *Malassezia*, and some bacteria. Some anti-inflammatory activity	b.i.d.
Others			
Tolnaftate	Inhibits squalene epoxidase	Dermatophytes, *Malassezia*	b.i.d.
Selenium sulfide	Cytostatic effect on keratinocytes Fungicidal against *Malassezia*	*Malassezia*	q.d.

spectrums of antifungal activity. Not only effective against *Candida*, they also inhibit dermatophytes and *Malassezia* (De Doncker et al. 1996; Odom et al. 1996; Elewski et al. 1997; Havu et al. 1997; Scher 1999). Additionally, topical econazole appears to exhibit some antibacterial activity (Brooks 1996; Rupke 2000). Their fungistatic properties are due to inhibition of the cytochrome P450-dependent enzyme, lanosterol 14α-demethylase, an important step in the synthesis of ergosterol. Ergosterol is vital for fungal cell membrane integrity.

The inhibition of the cytochrome P450 enzyme system can lead to significant drug interactions when the systemic azoles are taken with other drugs metabolized by these enzymes, such as astemizole, some benzodiazepines, cisapride, cyclosporine, warfarin, and the statins. Medications such as antacids, proton-pump inhibitors, and H_2-blockers may decrease the systemic absorption of ketoconazole and itraconazole by raising the gastric pH. These drugs are better absorbed when taken with food or an acidic beverage. By contrast, fluconazole can be taken without regard to food.

Following oral administration and absorption, both fluconazole and itraconazole achieve excellent tissue distribution. Fluconazole is hydrophilic and is widely distributed throughout the body. It has been detected in the skin and nails within 2–3 hours of oral administration (Haneke 1990, 1992; Hay 1993; Scher 1999; Moossavi et al. 2001). Therapeutic levels remain in the stratum corneum for at least one week after treatment (Wildfeuer et al. 1994; Lesher 1999). In contrast to fluconazole, itraconazole is highly lipophilic. It also has a strong affinity for keratin, resulting in persistently high concentrations is the stratum corneum and in nails. Significant drug levels have been found in the stratum corneum from the back, palms and face for 2, 3, and 4 weeks, respectively, after stopping therapy (Cauwenbergh et al. 1988; Lesher 1999). A level far exceeding the minimum inhibitory concentration (MIC) of common dermatophytes was detected in nails 90 days after completing a 7-day course (Meinhof 1993; Scher 1999). This preferential persistence in keratin permits dosage flexibility such as once weekly administration of fluconazole as well as 'pulse' dosing of itraconazole.

Adverse effects of the topical azole antifungal agents are generally limited to local irritation, stinging, burning, and contact dermatitis. However, gastrointestinal adverse events are not uncommon with the oral agents. Indeed, approximately 10 percent of patients taking itraconazole or ketoconazole may report nausea or vomiting (Moossavi et al. 2001), which can be improved by dosing with meals. Gastrointestinal symptoms are also seen with fluconazole, although less frequently. Six percent of the patients taking fluconazole in a study reported in 1998 experienced headache, which was the most frequently reported adverse effect (Scher et al. 1998). Itraconazole has recently been associated with a nega-

tive inotropic effect on the heart and congestive heart failure. It is contraindicated in patients with known ventricular dysfunction (Ahmad et al. 2001). The most worrisome adverse effect seen with systemic azole therapy is hepatotoxicity. The incidence of ketoconazole-induced hepatotoxicity ranges from 1:10 000 to 1:15 000 and has been fatal in at least seven people. The hepatotoxicity seems to be idiosyncratic and is not related to the dose or length of therapy (Knight et al. 1991; Moossavi et al. 2001). This, combined with the significant drug interactions, has effectively ended frequent systemic use of ketoconazole for cutaneous fungal infections. Serum transaminases may also be elevated with itraconazole (Tucker et al. 1990) and less frequently with fluconazole (Scher et al. 1998). Monitoring of hepatic enzymes is recommended in patients taking itraconazole continuously for longer than one month and in those with preexisting hepatic function abnormalities (Mehta 2001; Moossavi et al. 2001) but routine monitoring is generally not required with fluconazole.

Allylamines/butenafine

A third group of antifungals is composed of the allylamines (topical naftifine and topical/oral terbinafine) and a single topical benzylamine (butenafine) (see Table 1).
Like the azoles, these agents have broad antifungal spectrums, and they have the additional advantage of fungicidal activity. This activity is due to their inhibition of squalene epoxidase, an enzyme needed for the production of ergosterol. As a result, squalene accumulates, producing a toxic effect on the organism and eventual cell death (Ryder 1992). It is still unclear if the in vitro fungicidal activity is clinically relevant.

Unlike the azole family, oral terbinafine does not affect the cytochrome P450 3A4 isoenzyme, so drug interactions are less problematic. Cimetidine may increase the levels of terbinafine by decreasing its metabolism and clearance. Conversely, rifampin induces hepatic metabolism of terbinafine and causes decreased blood levels. The combination of cyclosporine and terbinafine may increase the clearance of cyclosporine. Terbinafine does inhibit cytochrome P450 2D6, which may lead to toxic levels of tricyclic antidepressants and thioridazine.

Terbinafine is well absorbed after oral administration and absorption is not affected by administration with food. Delivery to the stratum corneum occurs rapidly. Levels were detected in peripheral nail clippings of healthy volunteers after 7 days of 250 mg/day dosing (Gupta et al. 1997; Scher 1999). The concentrations in the stratum corneum of patients taking the 250 mg/day dose for 1 or 2 weeks were far greater than the MICs of most dermatophytes (10–100 and 100–1 000, respectively) (Faergemann et al. 1994; Lesher 1999). Similarly, the drug level in nails 90 days after completing one week of therapy was much higher than the MICs (Gupta et al. 1997; Scher 1999).

As with other oral antifungals, gastrointestinal side effects are among the most commonly reported with terbinafine. Hepatic adverse effects range from transient elevations of serum transaminases in 3.3–7 percent of patients to severe cholestatic or hepatocellular hepatotoxicity (Boldewijn et al. 1996; Moossavi et al. 2001). This is thought to be an idiosyncratic, nondose-related reaction. Rarely, severe cutaneous events have been reported with terbinafine including toxic epidermal necrolysis, erythema multiforme, Stevens–Johnson syndrome, and acute generalized exanthematous pustulosis (Moossavi et al. 2001). The topical agents are well tolerated. Adverse effects such as allergic or irritant contact dermatitis, itching, burning or stinging have rarely been reported (Phillips and Rosen 2001).

Griseofulvin

Griseofulvin was the first widely used systemic antifungal medication. Its spectrum of activity is limited to dermatophytes and it is ineffective against *Candida*, *Malassezia*, bacteria, deep fungal infections, and nondermatophyte molds such as *Scopulariopsis* and *Scytalidium* (Moossavi et al. 2001). Griseofulvin's fungistatic activity is due to interference in microtubule spindle formation in actively growing fungi. Poor absorption from the gastrointestinal tract is counteracted by microsizing or ultramicrosizing griseofulvin particles. The ultramicrosized particles are better absorbed and require lower dosages. Absorption is also enhanced by administration with a fatty meal. Drug interactions are generally due to griseofulvin's induction of the cytochrome P450 enzyme system with resultant decreased blood levels of other drugs metabolized by this system. Examples include warfarin, oral contraceptives, and salicylates. Headache is the most common adverse effect and this usually resolves with continued therapy. Although rare, hepatotoxicity, neutropenia, and leukopenia have been reported.

Miscellaneous antimycotic agents

CICLOPIROX

Ciclopirox is a broad-spectrum topical antifungal which is effective against dermatophytes, yeasts, fungal saprophytes, and some gram-positive and gram-negative bacteria (Jue et al. 1985) (see Table 1). In addition, it has some anti-inflammatory activity and may be especially useful in treating superficial inflammatory mycoses (Hanel et al. 1991). It acts by altering active membrane transport, cell membrane integrity, and cell respiratory processes (Abrams et al. 1991; Phillips and Rosen 2001).

It is available as a cream, gel, lotion, nail lacquer, and shampoo.

TOLNAFTATE

Tolnaftate is a topical antifungal with a narrow spectrum of activity (see Table 1). It is effective in superficial infections caused by dermatophytes and *Malassezia*, but is not active against *Candida* or bacteria (Gupta et al. 1998; Weinstein and Berman 2002). It inhibits squalene epoxidase, thus interfering with fungal cell wall sterol synthesis (Phillips and Rosen 2001).

SELENIUM SULFIDE

Selenium sulfide is a liquid topical antifungal agent used in the treatment of tinea versicolor and seborrheic dermatitis (Sanchez and Torres 1984; Faergemann 2000) (see Table 1). It has some in vivo fungicidal activity against *Malassezia* (Phillips and Rosen 2001). It also appears to have a cytostatic effect on keratinocytes, which may explain its effectiveness as an adjutant in the treatment of tinea capitis (Allen et al. 1982; Givens et al. 1995).

Choice of agent

Topical antifungal agents can be used as sole therapy in most superficial fungal infections. They offer the advantages of very few adverse effects and negligible systemic absorption. For these reasons, they are generally considered first-line therapy except in tinea capitis and onychomycosis, which do not respond well to topical therapy and require treatment with an oral agent. Other instances in which systemic antifungal therapy may be required include:

- failure of topical agents
- patients immunocompromised by disease or therapy
- extensive fungal disease.

THERAPY OF SELECTED SUPERFICIAL INFECTIONS

Malassezioses

TINEA VERSICOLOR

Tinea versicolor usually responds well to topical therapy. Selenium sulfide 2.5 percent, ketoconazole 2 percent, or zinc pyrithione 1 percent shampoos/lotions can be applied to the affected areas and left in place for 5–10 minutes once a day for 2 weeks. Alternatively, the azole antifungal creams or ciclopirox 0.1 percent solution are also generally effective when used twice daily (Corte et al. 1989).

Failure of the above regimens or extensive disease may force trial of systemic medications (see Table 2).

Table 2 *Systemic antifungals for tinea versicolor*

Drug	Dosage
Fluconazole	400 mg once 400 mg once and repeat in 7 days
Itraconazole	200 mg/day for 7 days
Ketoconazole	200 mg/day for 5–7 days 400 mg once and repeat in 7 days

Ketoconazole 200 mg/day for 5–7 days has been proven effective. One study showed 17 of 23 patients treated with fluconazole in a 400 mg one-time dose were clear of lesions 3 weeks after treatment (Faergemann 1992). Another study found itraconazole 200 mg/day for 7 days to be safe and effective (Hickman 1996). Oral terbinafine does not appear to be effective in treating tinea versicolor (Lesher 1999).

As many as 60–80 percent of patients successfully treated with oral or topical therapy will have a recurrence of tinea versicolor within one year (Rupke 2000). To reduce this rate, appropriate prophylaxis may be necessary. A single dose of oral ketoconazole, fluconazole, or itraconazole could be dosed once or twice a month. Topical antifungal agents may also be used once or twice monthly. In either case, however, compliance may be an issue.

SEBORRHEIC DERMATITIS

Although the role of *Malassezia* in the etiology of seborrheic dermatitis is unclear, agents effective against these organisms are also generally effective in controlling this condition. Ketoconazole 2 percent shampoo has been successful when applied at least twice a week (Peter and Richarz-Barthauer 1995). Ciclopirox 1 percent, selenium sulfide 2.5 percent shampoo (Shuster 1984) and zinc pyrithione shampoo (Marks et al. 1985) have also worked well. Antifungal creams offer another therapeutic option. Due to its anti-inflammatory activity, ciclopirox may be particularly useful in seborrheic dermatitis (Hanel et al. 1991). Nonantifungal treatments for seborrheic dermatitis on the face include low-potency topical corticosteroids such as desonide, hydrocortisone, or alclometasone. More potent corticosteroid lotions, solutions, or foams may be used on the scalp. The topical immunomodulating agent, pimecrolimus may prove to be effective (Ling 2001; Crutchfield 2002).

PITYROSPORAL FOLLICULITIS

Pityrosporal folliculitis usually responds well to topical treatment with an azole cream or shampoo. Selenium sulfide shampoo/lotion may also be used (Ford et al. 1982). When patients do not respond to topical therapy, oral fluconazole (100–200 mg/day for up to 3 weeks), ketoconazole (200 mg/day for 7–10 days), or itraconazole (200 mg/day for 5–7days) may prove effective (Ford et al. 1982; Rhie et al. 2000). Itraconazole may be the

most effective option because its lipophilic properties permit penetration into the pilosebaceous unit.

Other superficial mycoses

TINEA NIGRA

Topical azole antifungals such as ketoconazole, econazole, or miconazole are normally sufficient for clearing tinea nigra (Marks et al. 1980; Burke 1993; Hughes et al. 1993). Ciclopirox and terbinafine have also been effective when used topically (Sayegh-Carreno et al. 1989; Shannon et al. 1999). Whitfield's ointment is an old medication that has also been used successfully. Some authors have suggested scraping away the visibly affected area before topical application (Sayegh-Carreno 1989). Oral therapy is rarely required.

PIEDRAS

Both black and white piedra may be treated by shaving or clipping off the infected hairs. This is not always a cosmetically acceptable therapy, however. Ketoconazole 2 percent shampoo, ciclopirox solution, selenium sulfide, and zinc pyrithione have been used with varying degrees of success. A small study reported complete cure in 11 of 12 patients with white piedra treated with 100 mg of itraconazole taken by mouth once daily for 8 weeks (Khandpur and Reddy 2002).

Dermatophytoses

TINEA CORPORIS AND TINEA CRURIS

Most topical antimycotics are effective in treating uncomplicated cases of tinea corporis and tinea cruris when used as directed by the manufacturer (Drake et al. 1996a; Brodell and Elewski 1997). See Table 1 for a list of these medications, as well as dosing frequencies. Nystatin is ineffective against dermatophytes and would therefore not be a good choice in treating tinea corporis (Lesher 1996). In intertriginous areas, tolnaftate should not be used, as it is not effective against *Candida* (Demis 1999). When bacterial superinfection is also suspected, topical antifungals with some antibacterial activity, such as econazole or ciclopirox, may be particularly useful (Drake et al. 1996a). All topical agents should be applied to the lesion and an approximately 2.5 cm border of surrounding normal skin. Ideally, application should be continued for 1–2 weeks after all signs of infection have cleared in order to minimize recurrence. More specific dosing suggestions can be found in the manufacturer's recommendations.

Indications for systemic therapy include failure of topical antimycotic agents, extensive disease, primary or secondary immune deficiency, and inflammatory infections such as Majocchi's granuloma. In addition, severely obese persons with tinea cruris may require systemic therapy. Suitable oral medications include griseofulvin, fluconazole, itraconazole, and terbinafine (Lambert et al. 1989; Lesher 1999) (see Table 3).

Due to the ubiquity of the pathogens, reinfection and recurrence are common. Simple strategies to minimize recurrence in patients with intertriginous dermatophytoses such as tinea cruris include keeping the area dry in order to make the environment less conducive to fungal growth. In addition, patients should avoid tight-fitting, nonabsorbent clothing and minimize exposure to wet clothing such as bathing suits. Affected areas should be dried thoroughly after bathing and hand-held hair dryers work well for this purpose. Other suggestions might include application of absorbent antifungal powders and weight reduction.

TINEA BARBAE

Although some cases of inflammatory tinea barbae may resolve spontaneously, alopecia and scar formation can occur. The less common, noninflammatory sycosiform variant rarely heals without therapy. Since the hair follicles are infected, systemic therapy is required (Drake et al. 1996a). Griseofulvin, fluconazole, itraconazole, and oral terbinafine have all been used successfully (see Table 4). In most cases, therapy should be continued until all lesions have cleared and new hair growth is occurring.

Adjunctive therapies may be of some benefit. Warm compresses may soften crusts and help in the removal of debris. Ketoconazole 2 percent or selenium sulfide 2.5 percent shampoos also help remove debris and may provide some antifungal activity.

Since most cases of tinea barbae are acquired from zoophilic sources, avoidance, identification, and treatment of infected animals are important.

TINEA PEDIS AND MANUUM

Interdigital tinea pedis and tinea manuum with no associated onychomycosis in immune competent patients generally respond well to topical antifungals. See Table 1 for a list of suitable agents along with their dosing frequencies. Antifungals with antibacterial

Table 3 *Systemic antifungals for tinea corporis and tinea cruris*

Medication	Dose
Fluconazole	50–100 mg daily or 150 mg once weekly for 2–3 weeks[a]
Itraconazole	100 mg daily for 2 weeks or 200 mg daily for 7 days[a]
Terbinafine	250 mg daily for 1–2 weeks[a]
Griseofulvin	Microsize 20 mg/kg/day for 2–4 weeks Ultramicrosize 15 mg/kg/day for 2–4 weeks

a) Lesher (1999)

Table 4 *Systemic antifungals for tinea barbae*

Drug	Dose
Griseofulvin	Microsize 20 mg/kg/day Ultramicrosize 15 mg/kg/day Continue for at least 2 weeks after resolution. Six weeks or longer are generally required
Fluconazole	150–300 mg once a week for 4–6 weeks or 200–400 mg daily for up to 4 weeks
Itraconazole	400 mg/day for 1 week. May require a second 1-week pulse 3 weeks after the first pulse is completed or 200 mg/day for 2–4 weeks
Terbinafine	250 mg/day for 2–4 weeks

activity, such as econazole and ciclopirox, are good initial choices as interdigital disease is often complicated by secondary bacterial infections (Rupke 2000). Activity against *Candida* may also be important and drugs such as tolnaftate, which lack this attribute, are not first-line (Drake et al. 1996b). Generally, topical antifungal agents should be used for about 4 weeks or as directed by the manufacturer. Topical terbinafine and butenafine may be effective in as little as one week of therapy (Villars and Jones 1989; Bergstresser et al. 1993; Savin et al. 1994, 1997; Elewski et al. 1995). Emollients containing lactic acid or urea may be useful adjuncts to the antifungals when extensive scaling or hyperkeratosis is present.

Systemic antifungals are generally required in moccasin and inflammatory tinea pedis. Other patients who may require oral therapy include those with concomitant onychomycosis, peripheral vascular disease, or compromised immune status. Griseofulvin may be ineffective in tinea pedis (Moossavi et al. 2001) but terbinafine, itraconazole, and fluconazole have all been used successfully (Lesher 1999) (see Table 5). When

Table 5 *Systemic antifungals for tinea pedis*

Drug	Dosage
Fluconazole	150–300 mg once a week for up to 8 weeks (Lesher 1999)
Itraconazole	100 mg/day for 2 weeks or 400 mg/day for 1 week
Terbinafine	250 mg/day for 1–2 weeks

onychomycosis is present, the nail infection should be treated to prevent recurrence of tinea pedis or tinea manuum. See Table 6 for medications and dosages used in treating onychomycosis.

As with other dermatophytoses, efforts to minimize exposure to the infective fungi help to prevent initial or recurrent infections. Protective footwear should be worn in public facilities such as locker rooms and hotel bathrooms. Taking measures to eliminate the warm, moist conditions in which dermatophytes thrive can also reduce the recurrence rate. For example, patients should be instructed to dry feet thoroughly after bathing, and to apply an antifungal powder to both the feet and inside shoes. The use of cotton socks wicks moisture away from the feet. Prevention and effective treatment of tinea pedis is likely to prevent tinea manuum and tinea corporis.

TINEA UNGUIUM (ONYCHOMYCOSIS)

Topical therapy of onychomycosis is often unsuccessful. Ciclopirox 8 percent in nail lacquer applied daily to infected nails for 48 weeks produced a complete cure in only 5.5 percent of patients in one study and 8.5 percent in another (Dermik Laboratories 2000; Mehta 2001). Evaluations of other topical agents are ongoing.

Due to the low efficacy of topical medications, oral antifungals are generally required (Drake et al. 1996b). Fluconazole, itraconazole, and terbinafine are options. See Table 6 for dosage and monitoring guidelines. Continuous terbinafine therapy has been shown to be more effective when compared to both pulsed and continuous itraconazole (Brautigam et al. 1995; De

Table 6 *Systemic antifungals for onychomycosis*

Drug	Dosage	Duration	Monitoring
Fluconazole	150–300 mg once a week	3 months for fingernails, 6 months for toenails. Some authors recommend 6–9 months	Generally none recommended
Itraconazole	Intermittent (pulse) dosing – 200 mg b.i.d.	One week per month for 3 consecutive months for toenails, 2 months for fingernails	Baseline LFTs. Monitor LFTs every 4–6 weeks for continuous dosing of more than 1-month duration (Rodgers and Bassler 2001)
	Continuous dosing – 200 mg q.d.	8 weeks for fingernails, 12 weeks for toenails	
Terbinafine	250 mg/day	6 weeks for fingernails, 12 weeks for toenails	Baseline liver function tests (LFTs) and complete blood count (CBC). Repeat monthly (Rodgers and Bassler 2001)

Backer et al. 1998; Evans and Sigurgeirsson 1999). A large North American study showed terbinafine to have the greatest in vitro activity against dermatophytes and nondermatophyte molds when compared to fluconazole and itraconazole. Itraconazole had the greatest activity against *Aspergillus* spp. and *Candida parapsilosis*. Fluconazole was the most active of the three against *Candida albicans* (Ghannoum et al. 2000). Although its use appears to be growing, there are few data available comparing the clinical efficacy of fluconazole to the other agents. Griseofulvin is used infrequently due to its low cure rates, high recurrence rates, and the need for protracted treatment courses. Likewise, oral ketoconazole is rarely used due to its hepatotoxicity.

In addition to systemic antifungal therapy, certain adjunct measures may provide additional benefits and help recurrent infections. Occasionally, a nidus of infection (dermatophytoma) may form under the nail, which responds poorly to current therapy and may require nail avulsion. Topical antifungals may also be useful, especially when patients have severe tinea pedis. The patient should be instructed to wear protective footwear in public showers and facilities and to avoid sharing manicure equipment and other fomites. Feet should be kept as dry as possible. Patients should be advised to wear cotton socks and to change them regularly. Antifungal powders help keep feet dry and may provide some therapeutic benefit. Finally, early recognition and effective treatment of tinea pedis will help prevent tinea unguium.

TINEA CAPITIS

Topical treatment of tinea capitis is considered ineffective as sole therapy and systemic therapy is required for penetration of hair follicles (Elewski 1999). See Table 7 for medications, dosages, and duration of therapy. Griseofulvin has been the gold standard and remains an effective alternative. In the USA, the microsized preparation is available in a 125 mg/5 ml suspension, 250 mg tablets and 500 mg tablets. The ultramicrosized product has enhanced absorption and is available in tablets ranging from 125 mg to 330 mg in strength. Availability may be limited in some countries. Griseofulvin's disadvantages include its prolonged treatment course and relatively high dosage when compared to the newer antifungals. The bitter taste of the suspension makes compliance a problem. Nausea, vomiting, and headache are not uncommon adverse effects that may reduce compliance, as does the bitter taste of the liquid formulation. Perhaps as a result of these disadvantages, fluconazole, itraconazole, and terbinafine have become more commonly used to treat tinea capitis. The pleasant-tasting fluconazole suspension is especially appealing for children. It is available in 10 mg/ml and 40 mg/ml strengths. In addition, tablet strengths range from 50 to 200 mg. Precise dosing of itraconazole is more difficult. The liquid preparation should not be considered a substitute for the capsule due to the adverse effects associated with its cyclodextrin-containing vehicle. The inability to divide the 100 mg capsule makes accurate pediatric dosing problematic. Unlike fluconazole, itraconazole needs to be taken with food or a cola beverage to enhance absorption. Terbinafine may be taken with or without food. It is available only in 250 mg tablets that can be divided for administration to children. In tinea capitis caused by *Microsporum canis*, terbinafine may prove less effective than the other systemic alternatives (Mock et al. 1998). Tinea capitis caused by this organism generally requires longer treatment courses with any selected antimycotic (Hamm et al. 1999).

In addition to systemic therapy, use of topical medications may help minimize spread of the infection. Selenium sulfide 1 and 2.5 percent (Allen et al. 1982; Givens et al. 1995) and ketoconazole 2 percent shampoos (al-Fouzan et al. 1993; Greer 2000) are thought to reduce shedding of infected hairs and to stabilize infectious particles. Although there are fewer data on ciclopirox shampoo, it is likely to be equally efficacious. Patients should be instructed to use one of these several times a week. When feasible, family members should also use

Table 7 *Systemic antifungals for tinea capitis*

Drug	Pediatric dose	Adult dose
Griseofulvin	Microsized 20–25 mg/kg/day in single or divided doses for 8–12 weeks Ultramicrosized 15 mg/kg/day for 8–12 weeks	Same
Fluconazole	6 mg/kg/day for 3–6 weeks	200 mg/day for 3–6 weeks
Itraconazole	5 mg/kg/day for 4 weeks Most require 100 mg/day Very small children: 100 mg every other day *M. canis* may require 6–8 weeks	5 mg/kg/day Usually 200 mg/day for 4 weeks
Terbinafine	Weight 10–20 kg: 62.5 mg/day (1/4 tablet) Weight 20–40 kg: 125 mg/day (1/2 tablet) Weight > 40 kg: 250 mg/day (1 tablet) For 2–4 weeks *M. canis* may require 6–8 weeks	250 mg/day for 2–4 weeks

these shampoos, because they may be asymptomatic carriers (Elewski 2000). Other preventative measures include discarding fomites such as combs, brushes, and other hair accessories. When a zoophilic pathogen such as *M. canis* is isolated, an attempt to identify and treat the infected animal could prove beneficial.

Nondermatophyte molds

Treatment of onychomycosis caused by nondermatophyte molds such as *Scytalidium* spp., *Acremonium* spp., *Fusarium* spp. and *Scopulariopis* spp. is difficult. Topical antifungals are ineffective, as are systemic ketoconazole and griseofulvin (Gupta and Elewski 1996). A study published in 2000 showed that terbinafine had the highest in vitro antifungal activity against *Acremonium*, *Fusarium*, *Scopulariopsis*, and *Scytalidium* spp. when compared to fluconazole, itraconazole, and griseofulvin (Ghannoum et al. 2000). However, the clinical relevance is uncertain. Terbinafine and itraconazole have also shown some clinical efficacy against *Scopulariopsis brevicaulis* (Gupta et al. 2001). Avulsion may be the best option.

Superficial candidiasis

CANDIDAL PARONYCHIA

Chronic paronychia may be associated with *Candida* infection in some patients. However, one study has shown that treatment of chronic paronychia with a topical steroid (methylprednisolone aceponate) was more effective than systemic antifungal therapy with itraconazole or terbinafine (Tosti et al. 2002). Nevertheless, both topical and oral antifungals continue to be used with varying degrees of success. Topical imidazoles and polyene antifungal solutions, gels, or lotions are applied frequently over a prolonged course of therapy. Thymol 4 percent solution in acetone, isopropyl alcohol, or chloroform and sulfacetamide lotion have also been used (Hay 1999). Oral fluconazole and itraconazole are alternatives, but their effectiveness has not yet been established (Hay 1999). Patients should also be instructed to keep their fingers warm and dry.

CANDIDAL ONYCHOMYCOSIS

Systemic therapy is often required for microscopy, biopsy or culture-proven candidal onychomycosis. Itraconazole has been used successfully in three pulsed doses for toenails and two pulses for fingernails (Gupta et al. 2000). Weekly dosing of 150–300 mg of fluconazole should also be effective although few trials have been conducted. Terbinafine has unpredictable in vitro activity against *C. albicans* (Ryder et al. 1998) and has not shown consistently good results clinically (Rex et al. 2000).

CANDIDAL INTERTRIGO AND INTERDIGITAL CANDIDIASIS

In contrast to onychomycosis, topical therapy is usually sufficient for candidal intertrigo (including diaper dermatitis) and interdigital candidiasis. Topical allylamines, butenafine, or imidazoles are applied once or twice daily (Drake et al. 1996c). As in any intertriginous condition, it is important for patients to keep the area dry. This can be done by using a hair dryer and by applying an antifungal powder.

OROPHARYNGEAL CANDIDIASIS (THRUSH)

For immunocompetent patients, topical treatment of oropharyngeal candidiasis with nystatin or clotrimazole is generally effective. Nystatin suspension or lozenges are given four to five times a day in doses ranging from 100 000 to 500 000 units. Clotrimazole 10 mg troches are given five times a day. Immunocompromised patients may require systemic antifungals. Fluconazole or itraconazole are given in 100–200 mg daily doses for 5–10 days. The development of resistance to these drugs can be a problem, especially in patients with acquired immunodeficiency syndrome (AIDS). Generally, when patients fail to respond clinically, the medication dose is doubled. If they still do not respond, it is necessary to check the identity and MIC value of the organism and to change drugs (Hay 1999).

VAGINAL CANDIDIASIS

Topical antifungals are usually effective in treating vaginal candidiasis. Imidazole (miconazole, terconazole, etc.) or nystatin vaginal creams, tablets or suppositories are used for from 1 to 7 days. Alternatively, oral therapy with fluconazole (100 mg/day for 5–7 days or 150 mg once) (Hay 1999), or itraconazole (200 mg/day for 3 days or 200 mg b.i.d. for 1 day) (Sobel et al. 1998) is also effective.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Systemic therapy with fluconazole, ketoconazole or itraconazole is usually necessary for patients with chronic mucocutaneous candidiasis. Dosing strategies similar to those used for oropharyngeal candidiasis in immune suppressed patients are employed. Once remissions are induced, maintenance therapy is not used in order to reduce the development of drug resistance (Hay 1999).

CONCLUSION

Successful management of superficial fungal infections requires not only knowledge of the various antimycotic agents but also familiarity with adjunctive measures that can help reduce the chance of spread or reinfection. This chapter has been a discussion of these measures along with a summary of the indications, dosages, mechanisms of action, adverse effects, and drug interactions of the

most commonly used topical and systemic antifungal drugs. Some superficial infections respond well to therapy with topical medications alone. Others such as tinea capitis require systemic therapy. The newer oral agents such as fluconazole, itraconazole, and terbinafine offer greater efficacy, broader spectrums of activity and shortened treatment duration. Awareness of their limitations, potential adverse effects and drug interactions is essential for proper patient selection and monitoring.

White piedra, black piedra, and tinea nigra

G. SYBREN DE HOOG AND EVELINE GUÉHO

Etiologic agents	1	Black piedra	3
Ecology	1	Tinea nigra	4
White piedra	2	References	5

Superficial mycoses are defined as the development of fungal growth on epithelial tissues such as human hair, skin, or nails, without noticeable invasion of living tissue and without apparently provoking an immune response by the host. (The term 'pityriasis' is often preferred rather than 'tinea' because the latter term should properly be reserved for dermatophyte infections.) Ecologically, such mycoses are comparable to epiphytic or epilithic growth, i.e. superficial colonization of plants, wood, or stones, almost without making use of the supporting substratum. In the case of colonizers of human skin, utilization of products excreted by the host seems likely.

Two ecological categories can be distinguished in superficial fungi. Growth on the human body may be entirely coincidental, the fungus occupying a natural niche outside the human body. This is the case with *Hortaea werneckii* (*Phaeoannellomyces werneckii*), the causative agent of human tinea nigra, which is a halophilic fungus living in salt pans at subtropical coasts (Zalar et al. 1999). Alternatively, the mammalian body may be the natural habitat of the fungus. This is the case, for example, with members of the ascomycete genus *Piedraia*, which are unique in the fungal kingdom in that they complete their entire lifecycle, including production of ascospores, on hairs of living humans.

ETIOLOGIC AGENTS

White piedra is caused by species of *Trichosporon* Behrend, a genus of basidiomycetous arthroconidial yeasts. *Trichosporon* spp. are also known as agents of cutaneous and of systemic infections. Black piedra is caused by members of the ascomycete genus *Piedraia* da Fonseca and de Area Leão, which are exclusively known as agents of this particular disorder. Tinea nigra is caused by the single species, *Hortaea werneckii* (Horta) Nishimura and Miyaji [*Phaeoannellomyces werneckii* (Horta) McGinnis and Schell].

ECOLOGY

Commensal fungi assimilate compounds that are produced by the human body, without invasion of living tissue (de Hoog et al. 2000). They may also decompose dying or dead host remains without the need for the host itself to be present. As they are frequently found on humans and may form macroscopically visible colonies, the fungi under consideration have frequently been referred to as opportunistic pathogens. However, infections caused by most of the species treated in this chapter are rare, even in immunocompromised patients.

When the target compound is an integral part of the host, e.g. keratin assimilated by dermatophytes, adjacent living tissue can also be affected, and a gradual evolution towards true pathogenicity may be expected (Rippon 1985). In the presence of excreted target compounds, the fungi remain strictly superficial. This is the case with the agents of black piedra and of tinea nigra, and with members of the lipophilic genus *Malassezia* Baillon.

WHITE PIEDRA

Clinical presentation

White piedra is a non-inflammatory, non-invasive fungal growth on the outside of the hair shaft. Soft nodules are formed, which can easily be pulled off the hair. The nodules are white, pale greenish, or yellowish and are composed of compacted fungal elements (Figure 1). At the outside the elements produce rounded arthroconidia-like cells. The hairs are not invaded, but they may break if the fungi have been present for long periods.

White piedra is caused by several *Trichosporon* species. The infections may affect hairs on the head, in the axilla, or on the crural area. Human white piedra of the scalp occurs with a low incidence in temperate and subtropical climates (Kaplan 1959a; Gold et al. 1984). Hairs of the beard, eyelashes, eyebrows, and scalp may be affected. In the nineteenth century, the disorder may have been quite common in temperate climates, judging from the fact that patients harbored such infections for several years (Guého et al. 1992a). White piedra has also been observed on the fur of other mammals such as the horse and lower primates worldwide (Kaplan 1959a).

White piedra of the groin does not depend on personal hygiene (Gold et al. 1984; Kalter et al. 1986). At present, genital white piedra is surprisingly common in the Americas (Fischman et al. 1980; Benson et al. 1983; Kalter et al. 1986), Africa (Thérizol-Ferly et al. 1994a) and Europe (Stenderup et al. 1986). Smith et al. (1973) suspected that the disorder might be underdiagnosed, as a result of the site of infection. It is frequently accompanied by intertrigo (Thérizol-Ferly et al. 1994a), but it may also be strictly harmless (Benson et al. 1983; Ellner et al. 1991). Prevalence varies with socioeconomic background (Ellner et al. 1991), gender (Thérizol-Ferly et al. 1994a), sexual behavior (Torssander et al. 1985; Stenderup et al. 1986), and with race (Avram et al. 1987), although marked regional differences can be noted. The fungus may also colonize adjacent cotton fibers in underwear (de Almeida et al. 1990). Perhaps the warm and moist microclimate of groin and axilla is a major predisposing factor. Axillary white piedra has not been investigated in detail; it probably occurs with a comparable frequency.

Microbiology and identification

TRICHOSPORON ASAHII AKAGI

Colonies on Sabouraud's glucose agar (SGA) are dry, pustular, with a broad, deeply fissured, marginal zone and with a white, farinose covering at the center. Budding cells and lateral conidia are absent. Arthroconidia are regular and barrel shaped (Figure 2). Appressoria are absent. Guého et al. (1992a) found that documented strains from superficial mycoses mainly originated from animal white piedra; numerous other strains came from human cutaneous and deep infections.

TRICHOSPORON CUTANEUM (DE BEURMANN ET AL.) OTA

Colonies on SGA are moist and shiny, with a broad, fissured, marginal zone without farinose covering. Budding cells are abundant in primary cultures, but hyphae predominate after repeated transfer. Arthroconidia are cylindrical to ellipsoidal, and lateral conidia are present. The species is known only from a small collection of strains, among which is one originating from axillary white piedra.

TRICHOSPORON INKIN (OHO EX OTA) DO CARMO SOUSA AND VAN UDEN

Colonies on SGA are restricted, cerebriform, with no marginal zone, often cracking the agar medium. Budding cells and lateral conidia are absent. Arthroconidia are long and cylindrical, and appressoria are present (Figure 3). Sarcinae may be present in tissue; in vitro this is reproduced on media with high sugar content. The species is limited to hairs in the groin area.

Figure 1 *Nodules of white piedra caused by* Trichosporon inkin *on pubic hair. Magnification* × *940*

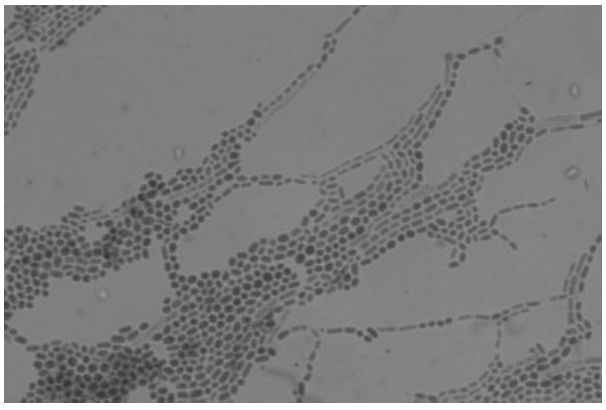

Figure 2 *Regular arthroconidia of* Trichosporon asahii. *Magnification* × *940*

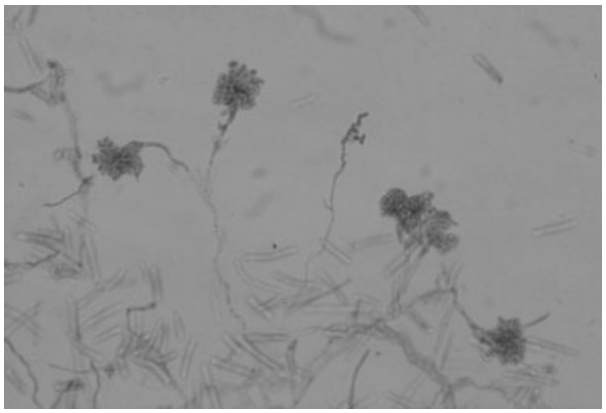

Figure 3 *Arthroconidia and appressoria of* Trichosporon inkin. *Magnification* × *940*

TRICHOSPORON MUCOIDES GUÉHO AND M.TH. SMITH

Colonies on SGA are moist and shiny, and elevated with deep, narrow, radial fissures. Arthroconidia are rectangular. Short lateral branches terminating with clavate conidia are present (Figure 4). The taxon is the prevalent species in groin infections of humans in Africa and is frequently isolated from other superficial locations in Europe.

TRICHOSPORON OVOIDES BEHREND

Colonies are white, farinose, and irregularly wrinkled at the center, with a flat marginal zone. Budding cells and lateral conidia are absent. Arthroconidia are cylindrical and appressoria are present. The species is physiologically indistinguishable from *T. asahii*. A strain originating from scalp white piedra, CBS 7556, was used as the neotype strain for the type species of the genus *Trichosporon* (Guého et al. 1992a).

DISCUSSION OF THE GENUS *TRICHOSPORON*

The genus *Trichosporon* has been revised using molecular characteristics (Guého et al. 1992b). A large number of species was recognized, several of which may be encountered as causative agents of opportunistic mycoses. Since that time several new species have been introduced (Sugita et al. 1997, 2001; Sugita and Nakase 1998; Middelhoven et al. 1999, 2000, 2001), but none of these is an agent of white piedra. Overviews of clinically relevant species were published by Guého et al. (1994) and Middelhoven (2002). It should be noted that the species involved in animal mycoses are different to those found in the environment. Thus, infections by *Trichosporon* spp. are probably transmitted through human or animal vectors.

Members of the genus have multilamellar cell walls in common and contain more or less developed dolipore septa, with or without vesicular or tubular parenthesomes (Guého et al. 1992b). They are therefore classified in the Basidiomycetes and are related to *Filobasidiella* (*Cryptococcus*), a position that has been confirmed by partial 26S rRNA sequencing (Guého et al. 1993) and antigenic similarity (Seeliger and Schröter 1963; McManus and Jones 1985). Nevertheless, the phylogenetic distance to remaining heterobasidiomycetes has been judged large enough to erect a separate order, the Trichosporonales (Fell et al. 2000).

Trichosporon spp. do not generally form budding cells but cubic or rectangular arthroconidia. Identification of the five species has been summarized by Guého et al. (1994) (Table 1; see Figure 1) and Therizol-Ferly et al. (1994b). Serological recognition of the three most prevalent species was demonstrated by Douchet et al. (1994).

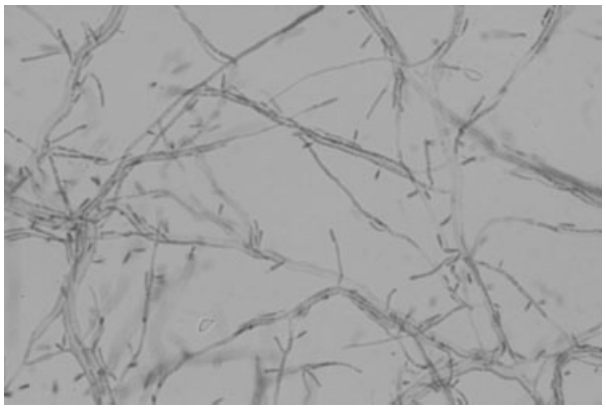

Figure 4 *Arthroconidia and lateral blastoconidia of* Trichosporon mucoides. *Magnification* × *940*

Therapy

The disorder can be controlled by shaving and local application of clotrimazole cream or 5 percent ammoniated mercury ointment (Kwon-Chung and Bennett 1992). All clinically significant *Trichosporon* spp. show high in vitro susceptibility to amphotericin B, clotrimazole, ketoconazole, and itraconazole (Kalter et al. 1986; Guého et al. 1994). Remissions of the disorder are, however, frequent (Walzman and Leeming 1989).

BLACK PIEDRA

Clinical presentation

Black piedra is an asymptomatic but macroscopically visible colonization of the shaft of scalp hair, caused by species of the ascomycete genus *Piedraia*. The species form hard, black nodules, consisting of dense fungal stromata, which are thicker (up to 150 μm) at one end. The nodules cannot be pulled off the hair shaft. The hairs may break after prolonged fungal growth. The disorder is restricted to humid tropical areas (Fischman

a) After a 4-day incubation at 25°C: –, no growth; +, growth in 24–48 h; s, growth in 72–96 h; v, variable growth. The five species are further separated by absence of growth at 37°C for *T. cutaneum* and no colonial margin for *T. inkin* (see Guého et al. 1994).

b) *T. ovoides*, responsible for the scalp hair white piedra, is the type species of the genus (Guého et al. 1992a).

et al. 1980), particularly South America (Coimbra and Santos 1989), Asia (Adam et al. 1977) and Africa, and may be associated with hair care involving the application of lipid-containing substances (Simons 1954). Black piedra commonly occurs on the pelts of primates living in tropical forests (Kaplan 1959b; Ajello 1964).

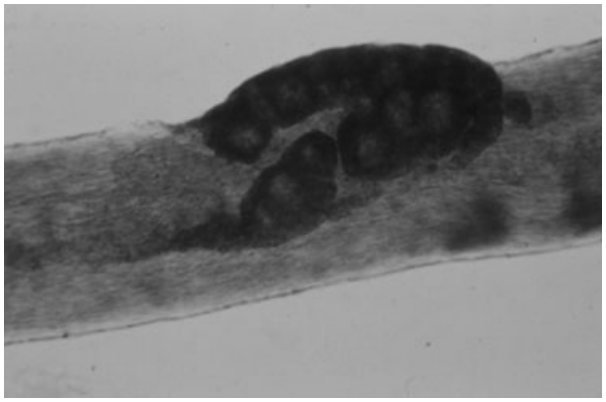

Figure 5 *Black piedra caused by* Piedraia hortae *on Asian scalp hair. The nodule corresponds to pseudoparenchymatous ascomata. Magnification × 940*

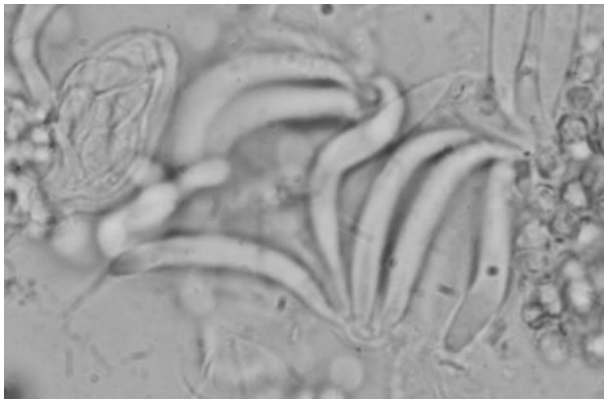

Figure 6 *Spindle-shaped ascospores of* Piedraia hortae *tapering towards both ends to form whip-like extensions. Magnification × 2 350*

Microbiology and identification

PIEDRAIA HORTAE (BRUMPT) DA FONSECA AND DE AREA LEÃO

Colonies on SGA containing glycerin grow slowly and are folded, velvety, and dark-brown to black; most remain sterile. Ascostromata on hairs are compact, elongated, up to 1 mm long and 0.3 mm wide. Black, spherical cavities (Figure 5) are formed by lysis, each containing a few broadly ellipsoidal asci, usually with eight ascospores (Figure 6). Ascospores are hyaline, one-celled, reniform (30–45 × 5.5–10 μm) with whip-like appendages at both ends.

DISCUSSION OF THE GENUS *PIEDRAIA*

A related species which does not produce ascospore appendages is *Piedraia quintanilhae* van Uden, reported from chimpanzees in Central Africa (Takashio and de Vroey 1975). It is not known to occur on humans.

Therapy

Treatment of black piedra is notoriously difficult, although topical application of azole antifungals or selenium sulfide has been used with variable degrees of success.

TINEA NIGRA

Clinical presentation

Brown to black lesions are formed, mainly on the skin of the palm (Severo et al. 1994), but occasionally on the sole of the foot. Pigmentation is more intense near the border. Only the outer, dead layers of the skin (stratum corneum) are affected; no invasion of living tissue occurs. The fungus is present in the form of melanized, ellipsoidal cells, which often have a thick median cross-wall.

Microbiology and identification

HORTAEA WERNECKII (HORTA) NISHIMURA AND MIYAJI

One of the synonyms is *Phaeoannellomyces werneckii* (Horta) McGinnis and Schell. Colonies on oatmeal agar are restricted, smooth, and slimy with an oily, glistening, olivaceous–black color. After several transfers the colonies may become velvety as a result of the production of aerial hyphae. Budding cells are subhyaline, 0–1 septate, and produce daughter cells by annellidic conidiogenesis from their poles. Hyphae are up to 6 μm wide, becoming thick-walled, olivaceous–black, and densely septate at maturation. Conidia are produced laterally from hyphae or from the poles of budding cells by annellidic conidiogenesis. Annellated zones are conspicuous and 1–2 μm wide, with clearly visible annellations. Conidia are initially hyaline and one-celled but soon become olivaceous and measure 7–9.5 × 3.5–4.5 μm. After liberation they inflate and develop transverse and occasionally oblique septa; liberated cells are converted into budding cells or chlamydospore-like cells (Figure 7).

DISCUSSION OF THE GENUS *HORTAEA*

The genus *Hortaea* contains two species. In addition to *H. werneckii*, which is halophilic (Zalar et al. 1999), *H. acidophila* has been introduced (Hölker et al. 2004), which is an extremophile able to grow in very acidic substrates. *H. werneckii* is recognized by resistance to 10 percent sodium chloride, production of extracellular DNAase (de Hoog and Gerrits van den Ende 1992), and by the presence of over 1 μm wide annellated zones with relatively widely spaced annellations (Miyaji and Nishimura 1985). Conidia soon become dark, swell, and develop transverse and oblique septa. Hyphae become dark and thick-walled with age and develop further transverse septa. The old hyphal cells are frequently wider than long, and finally produce extracellular granular material. Yeast-like strains without hyphae are recognized morphologically by bipolar annellated zones.

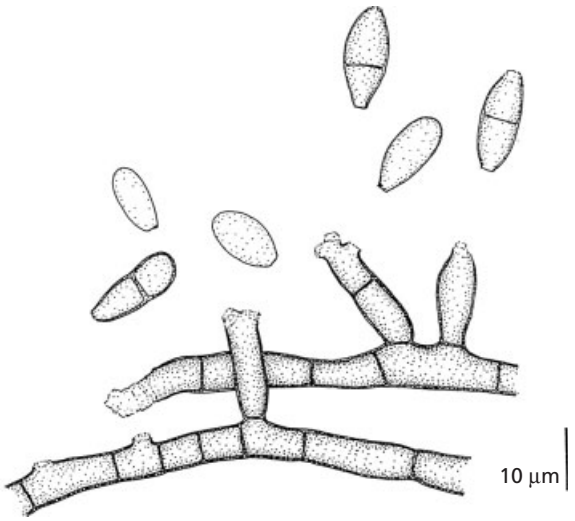

Figure 7 Hortaea werneckii*: morphology of 1-month-old culture on oatmeal agar.*

Phylogenetic position

The species was found to be phylogenetically related to *Aureobasidium pullulans* (De Bary) Arnaud (Haase et al. 1995; Spatafora et al. 1995), which may be an anamorph member of the ascomycete family *Dothioraceae* (order Dothideales). These findings are consistent with the similarities in karyology and thallus maturation (Takeo and de Hoog 1991), coenzyme Q systems (Yamada et al. 1989) and the absence of Woronin bodies at septal pores (Mittag 1993). The family contains plant-parasitic fungi and osmo- and acidophilic species living in the phyllosphere; numerous species occur on inert surfaces such as stone (Sterflinger et al. 1999). No human pathogenic species are known. Phylogenetically they are not related to the human pathogenic black yeasts classified in *Exophiala* Carmichael (Masclaux et al. 1995), which are anamorph members of the ascomycete family *Herpotrichiellaceae* (order Chaetothyriales).

Ecology

Hortaea werneckii is halophilic, its natural niche containing significantly elevated concentrations of salt, e.g. beach soil, salt pans, sea water, or salted fish (Zalar et al. 1999). The finding of this habitat confirms speculations of de Cock (1994) and Uijthof et al. (1994) based on mitochondrial DNA and molecular fingerprinting, respectively. Human cases are primarily reported from coastal areas in the subtropics (Rippon 1988). Hyperhydrotic humans may acquire the colonization of their skin. Primary adhesion may be explained by hydrophobic interaction of fungal cells with human skin; the fungus may subsequently thrive on the human body by the production of extracellular polysaccharides and feed by the assimilation of lipidic excretion products (Göttlich et al. 1995).

Similar behaviour may be adduced for the equally saprophytic fungus, *Stenella araguata* Sydow (*Cladosporium castellanii* Borelli and Marcano). This species was reported as an etiologic agent of cases of tinea nigra in Venezuela (di Prisco and Borelli 1973; Marcano and Hutton 1973; Reyes and Borelli 1974).

Therapy

The fungus can easily be removed by keratinolytic compounds such as Whitfield's ointment (Rippon 1988).

INTRODUCTION

Definition and history

The genus *Malassezia* comprises opportunistic lipophilic yeasts with a natural habitat on the skin of humans and warm-blooded animals. Their ability to cause diseases in humans was recognized more than 150 years ago, when Eichsted in 1846 stated that a fungus was responsible for the lesions of pityriasis versicolor (PV). However, the impossibility at this early stage of isolating and culturing the pathogenic agent brought a long-lasting nomenclatural and clinical controversy that was detailed by Slooff in 1970. As a short introductory history, Baillon created the genus *Malassezia* in 1889, with the species *Malassezia furfur* as the agent of PV. In the lesions, yeasts and filaments (= mycelium or hyphae) were observed, but in the absence of growth on isolation there was no certainty that both features were produced by a single microorganism. The genus *Pityrosporum* was thus created to accommodate similar yeasts observed, without any filaments, in the scales of the human scalp (*Pityrosporum ovale* Castellani and Chalmers 1913), rhinoceros skin (*Pityrosporum pachydermatis* Weidman 1925), and dog-ear (*Pityrosporum canis* Gustafson 1955). The species *Pityrosporum orbiculare* (Gordon 1951b) had been also described because of the morphological similarity of yeasts present in PV scales with those of the two former *Pityrosporum* species. The two species described in humans were found to require complex media to grow whereas the two zoophilic species were less demanding for lipids, growing on enriched media such as Sabouraud dextrose agar (also mycosel agar). The lipophilicity, which excluded the use of any yeast identification system, either conventional or commercial, led mycologists, in the absence of clear key characteristics, to limit this group of fungi to two species (Yarrow and Ahearn 1984): a human species *M. furfur*, and an animal species *Malassezia pachydermatis*, the generic name *Malassezia* having a nomenclatural priority to *Pityrosporum*. In 1990, Simmons and Guého described a third species *Malassezia sympodialis* on the basis of genome differences, but in the absence of well-defined differences, mycologists, and dermatologists as well, up to 1996 ignored this new species.

Phylogeny and taxonomy

The genus *Malassezia* was recognized as having basidiomycete characteristics, even although no teleomorph could be found for any of the species. These features included a multilayered cell wall, repetitive monopolar budding, and a capacity to hydrolyze urea and to give red staining with diazonium Blue B. These characteristics, combined with the lipophilicity, were the basis for a study involving the collection of as many fresh strains as possible from humans and animals, coupled with the

various isolates still available in international fungal collections, and for performing a taxonomic revision of the genus. The access to new molecular techniques, such as ribosomal RNA sequencing, allowed investigators to identify seven genetic species (Guillot and Guého 1995). In addition to the already known species *M. furfur*, *M. pachydermatis*, and *M. sympodialis*, the species *Malassezia globosa*, *Malassezia obtusa*, *Malassezia restricta*, and *Malassezia slooffiae* were thus added to the genus, all species having morphological and physiological key characteristics (Guého et al. 1996).

Then, the genus *Malassezia* with its seven species was confirmed as belonging phylogenetically to the Basidiomycota. These species form a branch, individualized as the order of Malasseziales, in the class of Ustilaginomycetes. However, and surprisingly, this branch is more closely related to plant pathogens such as *Exobasidium* spp. and *Tilletia* spp. (Begerow et al. 2000; Fell et al. 2000) than to the human and animal pathogens *Cryptococcus neoformans* and *Trichosporon* spp. classified as Tremellales and Trichosporonales, respectively (Sugita et al. 2002; Boekhout and Guého 2003).

The seven species can be easily identified in routine of medical laboratories, by combining their morphological and physiological characteristics (Guillot et al. 1996; Mayser et al. 1997; Guého et al. 1998). In cases of doubt, sequencing removes any ambiguity (Duarte et al. 2002). Furthermore, owing to the great reliability of sequences, several techniques for molecular identification of *Malassezia* yeasts can be developed (see section on Molecular methods of identification below).

These different techniques of identification have led already to a number of studies that have investigated the relationships of different species with both diseased and healthy skin. From some of these works (Crespo Erchiga et al. 1999a, b, 2000, 2002; Nakabayashi et al. 2000; Aspiroz et al. 2002), it now appears clear that *M. globosa* is the main species associated with PV. This is the only cutaneous disease in which the involvement of *Malassezia* is undisputed. Nevertheless, this species can also be found in normal skin, alone, or mixed with *M. sympodialis*, *M. restricta*, or *M. furfur* (Sugita et al. 2001). In the remaining dermatological disorders associated with *Malassezia* yeasts, their role is controversial. In seborrheic dermatitis, atopic dermatitis, and folliculitis, several studies have focused on the immunological aspects that might explain the pathogenic mechanisms (Ashbee et al. 1994a, b; Devos and van der Valk 2000; Kesavan et al. 2000; Koyama et al. 2000; Tengvall Linder et al. 2000; Faergemann et al. 2001; Ashbee and Evans 2002; Faergemann 2002). In other diseases, such as confluent and reticulate papillomatosis, neonatal pustulosis, psoriasis, blepharitis, otitis, and onychomycosis, the presence and/or significance of *Malassezia* is still a matter of discussion.

CHARACTERISTICS OF *MALASSEZIA* SPP.

Identification in vivo and isolation

The cutaneous pathologies caused by *Malassezia* yeasts are sufficiently characteristic to be identified readily by dermatologists. Usually, because they are not equipped to perform cultures, dermatologists do not isolate yeasts from lesions, but often they confirm their diagnosis with a direct microscopic examination of material from lesions. Indeed, the yeasts are among the smallest seen in tissues, but the repetitive unipolar budding leaves a very typical prominent bud scar on the mother cells. The most satisfactory method for visualizing this phenomenon can be performed when ink (Parker Permanent Blue/Black Quink) is incorporated with the classical 20–30 percent potassium hydroxide in equal proportions (Cohen 1954). *Malassezia* elements (yeasts and/or filaments) take up the stain immediately and appear blue against a clear background (Figure 1). A more selective staining method is the calcofluor white stain which can only be visualized if the laboratory has access to a fluorescence microscope. This technique provides an excellent view of seborrheic dermatitis and healthy skin samples (Figure 2). Indeed, the appearance of the fungus in tissues, including the yeast shape, the presence or absence of filaments, and the frequency of the two features, provides information about the disease itself. When just one species *M. furfur* (Yarrow and Ahearn 1984) was recognized in humans (alias *P. ovale* or *P. orbiculare*), and another, *M. pachydermatis* (alias *P. pachydermatis* and *P. canis*), in animals, further identification from cultures was not necessary. The interest in *Malassezia*-related pathology has resurrected recognition that several lipid-dependent *Malassezia* species are present in humans (and animals), and those that can be isolated from healthy or diseased skin.

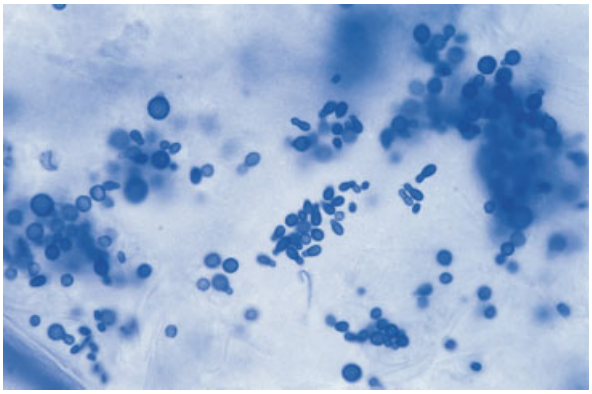

Figure 1 *Oval and globose yeasts in skin scales in a case of Gougerot–Carteaud disease. KOH+Parker ink, ×1 000*

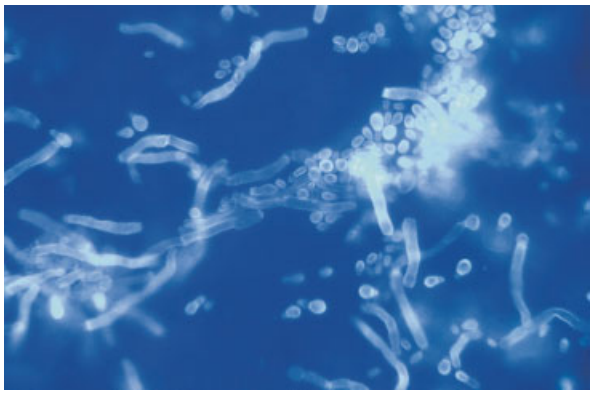

Figure 2 Malassezia *oval yeasts and pseudo-hyphae in healthy human skin from the paranasal area. Calcofluor white, ×1 000*

For years the lipophilic fungus *Malassezia* was isolated from skin scales, nails, or other infected materials on regular Sabouraud agar (2 percent glucose, 1 percent peptone, 2 percent agar) or 1 percent olive oil Sabouraud agar, both media supplemented with 0.5 percent chloramphenicol and 0.5 percent cycloheximide to eliminate, as much as possible, contamination by bacteria and molds, respectively. The regular Sabouraud medium was sufficient to isolate the lipophilic, but nonlipid-dependent, species *M. pachydermatis*, whereas the same medium enriched with 1 percent emulsioned olive oil seemed to be very convenient for isolation of the lipid-dependent species *M. furfur* (Guého and Meyer 1989). The taxonomic revision showed that olive oil could be toxic for a few species, so this medium, which is too selective, is no longer used. Two media are now widely employed to isolate and grow all *Malassezia* species: the Dixon medium described by van Abbe in 1964 or its modified formula (mDixon): 3.6 percent malt extract, 0.6 percent peptone, 2.0 percent desiccated ox-bile (Oxoid), 1.0 percent Tween 40, 0.2 percent glycerol, 0.2 percent oleic acid, and 1.2 percent agar, and the medium described by Leeming and Notman in 1987. Because *Malassezia* yeasts are a part of the cutaneous flora of warm-blooded animals, the addition of chloramphenicol and cycloheximide is recommended for all media. The advantage of the former medium (mDixon) over the latter (Leeming and Notman) is that its dark coloration makes easier counting of colonies, particularly when several species are mixed, and a better recognition of their morphologies. This is the reason that the present authors favor the mDixon rather the Leeming and Notman formula in their work. Moreover, before the taxonomic revision, cultures were almost systematically incubated at 37°C. As for the olive oil, the taxonomic revision has shown that several species are inhibited above 37°C. So all cultures are now performed between 30 and 35°C, according to the facilities of the laboratory, but never at 37°C or above, except to characterize the maximum temperature of growth.

Identification in vitro

The seven species of *Malassezia* were clearly separated genetically (Guillot and Guého 1995). However, they are easily identified with routine techniques in any microbiological laboratory on the basis of their characteristics, including their location on the body, colony and yeast morphology, maximum growth temperatures, β-glucosidase (splitting of esculin), and catalase activities, and requirements for growth, in other words growth with Tweens 20, 40, 60, 80, and cremophor EL as sole source of complex lipid. In the lead taxonomic paper (Guého et al. 1996), growth with Tweens at various concentrations was evaluated in liquid medium. Maximum temperatures of growth and catalase activity were fixed for all strains included in the study. Then a simplified method of identification was deduced from these basic results with the diffusion of Tweens in Sabouraud agar plates (Guillot et al. 1996). The identification scheme was improved by Mayser et al. (1997) who suggested the addition of cremophor EL to the diffusion plates and the characterization of the β-glucosidase activity using the esculin agar tubes. The complete identification system was finally summarized by Guého et al. in 1998 (see also Figure 3).

M. furfur forms thick, convex or umbonate colonies, 4–5 mm in diameter, with a surface that is smooth to rough and a cream color (Figure 4). The texture is soft and the cells are easy to emulsify. This is not the case for all species and, for eliciting this characteristic, it is important to prepare suspensions for all experiments. The species is morphologically heterogeneous with globose, oval, or cylindrical yeast cells (usually not in the same culture), 4.0–5.0 μm and up to 6.0 μm long, some strains being able to produce filaments, spontaneously or under particular culture conditions (Figures 2 and 5). These are now considered to be pseudohyphae since they have no dolipores, which interrupt the true filaments in Basidiomycetes (Guillot et al. 1995). This species is genetically heterogeneous with high ribosomal RNA similarity, but with two karyotypes (Boekhout et al. 1998). By contrast, *M. furfur* is physiologically homogeneous. It can be routinely identified by combining all its characteristics: ability to grow above 37°C, a strong catalase reaction, an absence or very weak β-glucosidase, and an equal growth in the presence of Tweens 20, 40, 60, 80, and cremophor EL as sole lipid (Figure 3). In fact, *M. furfur* is weakly lipid dependent since any lipid supplement is sufficient for its growth. Mayser et al. (1997) demonstrated this as castor oil and ricinoleic acid were sufficient for growth of *M. furfur*. Murai et al. (2002) showed also that *M. furfur* was the least dependent species with a unique positive effect on the growth with glycine. Specific characteristics are quite stable for all the species. However, atypical variants may occur, such as the *M. furfur* dog isolate,

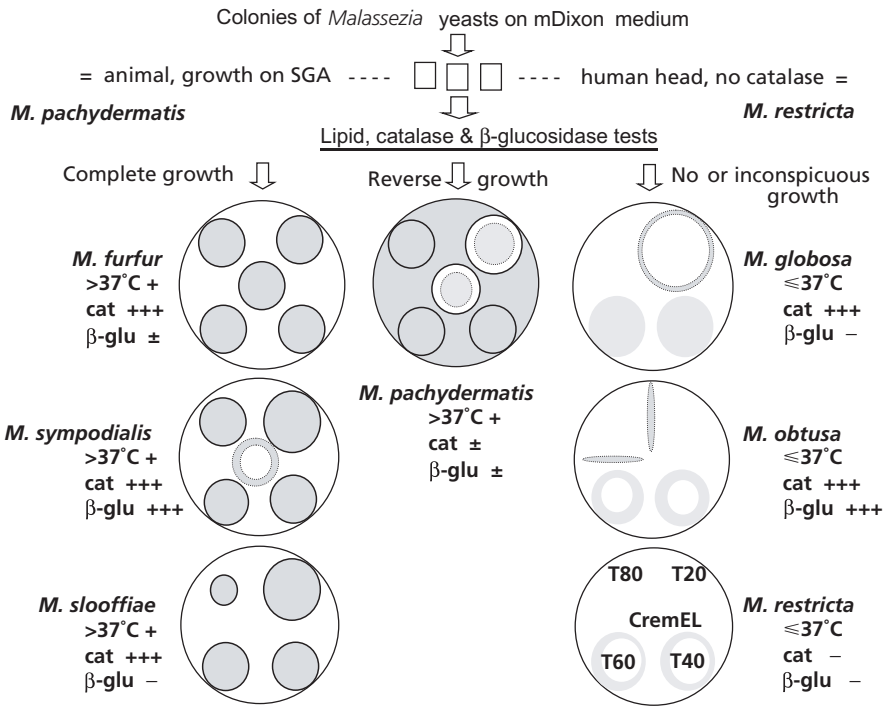

Figure 3 *Scheme of* Malassezia *spp. identification. Each culture isolated on mDixon agar is tested for its catalase (cat) and β-glucosidase (β-glu) activities; its growth at 37°C is given; then its capacity to grow with Tweens 20, 40, 60, 80, and Cremophor EL is evaluated using Sabouraud agar plates: complete growth (circled gray color); inconspicuous growth (dotted-circled gray color); only precipitate (not circled light gray color).*

confirmed specifically by rDNA sequencing, but unable to grow with cremophor EL (Duarte et al. 2002). Normal isolates of the species are also regularly, but not abundantly, isolated from various animals (Crespo et al. 1999, 2002).

M. pachydermatis is historically the second species described in the genus. It is different from all the other species since it is able to grow on rich conventional laboratory media (Sabouraud or mycosel agars). The species is lipophilic but can grow in the presence of simple lipids present in the peptone of such media. *M. pachydermatis* grows also on mDixon agar and generates thick, cream-colored, and convex colonies with a mat surface and usually a brittle texture which makes it difficult to emulsify (Figure 6). The cells are small, 2.5–4.0 μm, oval to short, and cylindrical with a very broad base to the bud (Figure 7). Pink isolates (Midgley 1989) have been reported and a genotype, isolated from dogs, and characterized by smaller colonies, was shown to be lipid dependent in primary culture (Bond and Anthony 1995; Guillot et al. 1997). Duarte et al. (2002) isolated also an atypical lipid-dependent strain of *M. pachydermatis* that remained dependent on lipids even after transfers. Therefore, all epidemiologic surveys of

Malassezia yeasts, from animal or human sources, should utilize directly lipid-supplemented media. The taxonomic revision maintained a single genetic species (Guillot and Guého 1995) but many of its characteristics show that it may be in the process of speciation, a possible adaptation in host specificity (Midreuil et al. 1999). All isolates grow at 37°C, but differences occur in catalase and β-glucosidase expression, and the Tweens 20, 40, 60, 80, and cremophor EL growth tests. These different compounds, particularly Tween 20 and cremophor EL, may be more or less inhibitory, a secondary growth appearing around the wells after dilution of the substrate by diffusion (Guého and Guillot 1999, and Figure 3). This species is rare in humans, although it has been found to cause epidemics of sepsis, usually in infants as a complication of prematurity (Mickelsen et al. 1988). In humans its isolation from skin may be considered as accidental. By contrast, the species is likely to be responsible for seborrheic dermatitis and otitis in warm-blooded animals, especially dogs (Guillot and Bond 1999).

M. sympodialis is an easy species to identify. It forms extended, up to 5–6 μm in diameter, flat colonies, often with a slight central elevation. These are cream to buff in color with a smooth, shiny surface, and a homogeneous texture, and are very easy to emulsify (Figure 8). The yeasts are small, 2.5–5.0 μm, and ovoid with a narrow bud base (Figure 9). As a result of sympodial budding at the same site, yeasts may remain somewhat grouped as 'clover leaves'. The species correlates with the former *M. furfur* serovar A (Cunningham et al. 1990). It grows at 37°C and it is easily characterized in routine by a strong β-glucosidase activity, which deeply darkens the esculin medium in 24 hours at 37°C, and the assimilation of the four Tweens, but only very weakly of cremophor EL (Figures 3 and 12.10). Primary isolates may develop a ring of tiny colonies at some distance from the cremophor source, as also seen in a few *M. slooffiae* isolates, but this latter species does not split esculin.

Sugita et al. in 2002 isolated and described a new species, *Malassezia dermatis*, from patients with atopic dermatitis. Analysis of ribosomal DNA 26S and internal transcribed spacers (ITS)s sequences showed this species to be closely related to *M. sympodialis*. The two species differ by only 1.2 percent rDNA base divergence, a difference acceptable as occurring within a single species (Kurtzman and Blanz 1998), and their colony

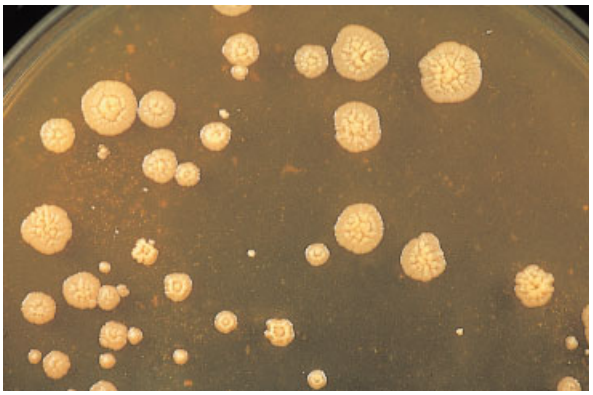

Figure 11 *Typical wrinkled colonies of* M. globosa*, 7 days old, on mDixon medium*

characteristics, but they cannot be separated with the basic laboratory tests (Guillot et al. 1996). *M. dermatis*, as with *M. sympodialis*, has strong catalase activity and assimilates the four Tweens. However, esculin and cremophor EL are missing in the description of this new species. Similarly, several horse *Malassezia* isolates were found with a rDNA sequence analysis that would suggest that they represent two new species (Nell et al. 2002). No description was given in the paper, although *Malassezia equi* was suggested as the name of one of these new species. As with *M. dermatis*, these zoophilic entities are very closely related to *M. sympodialis* phylogenetically. More studies are in process to better characterize and possibly validate these different entities. *M. nana*, another new species isolated from animals, also resembles *M. sympodialis* but does not split esculin (Hirai et al. 2004). The species *sensu stricto* was found to be associated with otitis externa in two cats (Crespo et al. 2000a).

M. globosa corresponds morphologically to the original description of *P. orbiculare* given by Gordon (1951a). This specific name was not preserved, because it was obvious that most data published in the past as *P. orbiculare* corresponded to one or the other lipid-dependent species. Immunologically, *M. globosa* correlates with the former serovar B (Cunningham et al. 1990). The species produces recognizable colonies, 4 mm in diameter, rough with a deeply folded surface, cream to buff in color, and a very brittle texture; they are particularly difficult to emulsify (Figure 11). The cells are spherical, reaching in some strains 6–8 μm in diameter with buds formed on a narrow base (Figure 12). In PV skin scales, these yeasts are regularly mixed with pseudofilaments, which are usually still present in primary cultures as germinative tubes, but unfortunately they disappear after several transfers. The species does not grow at 37°C, or very poorly, does not split esculin, and does not grow with any individual lipid supplements (Figure 3). Fresh isolates may produce tiny colonies in the presence of Tweens, in particular Tween 20. Whitish disks, frequently present with the different species, around Tweens 40 and 60 correspond to precipitates (Guillot et al. 1996). *M. globosa* is very often associated with another species, especially *M. sympodialis*, but also *M. furfur*, *M. slooffiae*, or *M. restricta* (Crespo Erchiga et al. 1999b). It has been isolated occasionally from horses and domestic ruminants (Crespo et al. 2002).

M. obtusa is a species that may be confused with *M. furfur* morphologically but not physiologically. The species grows slowly, so colonies remain small in diameter with a sticky texture. By contrast, cylindrical cells are among the biggest in the genus, up to 10 μm long when the bud is still attached to the mother cell. The species does not grow at 37°C, or with any of the five lipids used as identification criteria as with *M. globosa* and *M. restricta*, but expresses strong β-glucosidase activity (Figure 3). It is a very rare species that so far is known to occur only in healthy skin. In animals it has been isolated, with *M. furfur*, from a case of canine otitis (Crespo et al. 2000b), and from healthy horses and goats (Crespo et al. 2002).

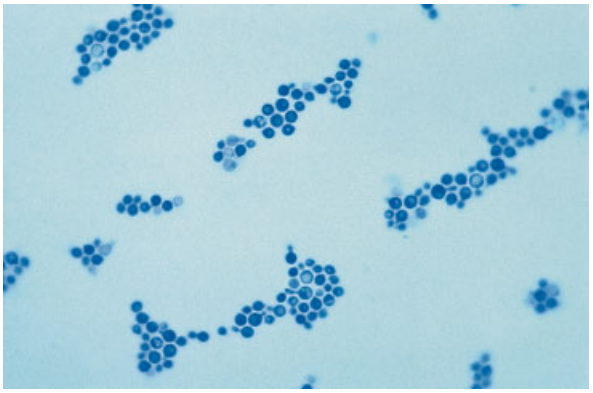

Figure 12 *Typical spherical yeast cells of* M. globosa*. Lactophenol Cotton Blue, ×1 000*

M. restricta might correspond to the former *P. ovale*, but it is difficult to correlate with the old literature, a task that is even greater than for *M. globosa*. The species was named 'restricta' because of its very poor performances. It grows very slowly, giving irregular, small (2 mm average in diameter) and cream-colored colonies with a hard texture; these are very difficult to emulsify (see Figure 8). Cells are spherical to oval, 2.0–4.0 μm, with buds formed on a relatively narrow base (Figure 13). Its micromorphology resembles that of *M. sympodialis*, but hopefully not its colonial macromorphology. This new species could be correlated with serovar C, the third serotype characterized by Cunningham et al. (1990) among lipid-dependent *Malassezia* yeasts. At this point it is important to point out that serotyping, as did biotyping proposed by Aspiroz et al. (1999), recognized only the three species *M. sympodialis*, *M. globosa*, and *M. restricta*, and ignored the others, in particular *M. furfur* and *M. slooffiae*. Hopefully for its identification, *M. restricta* is the only lipid-dependent species lacking catalase activity. This test is thus recommended as a first step, particularly when very restricted numbers of *Malassezia* colonies are obtained from the head. Furthermore, this species does not grow at 37°C, does not split esculin, and does not grow in the presence of different Tweens or cremophor EL (Figure 3). The species, as with *M. obtusa*, has also been isolated for the first time from domestic animals (Crespo et al. 2002). Because of the great difficulty encountered with this species, its presence in humans, and possibly in animals, is likely to have been underestimated. Furthermore, such difficulties in isolation, obtaining sufficient cultures, and maintaining *M. restricta* may be a barrier to understanding the dermatological disorders such as seborrheic dermatitis and atopic dermatitis, and consequently their treatment.

M. slooffiae, one of the four new species, is less frequently isolated from humans but appears to be regularly associated with the skin of pigs. It may be morphologically misidentified as *M. furfur*. It has colonies with finely folded margins, that are 3 mm in diameter, cream to buff in color, and have a brittle texture (Figure 14). The cells are small and shortly cylindrical, 1.5–3.5 μm long, but never globose or elongate as are some strains of *M. furfur* (Figure 15). However, physiologically, there is no ambiguity in clearly identifying organisms as *M. slooffiae*. The species has catalase activity and grows at up to 40°C as does *M. furfur*, but it does not split esculin at all, grows weakly with Tween 80, and does not grow with cremophor EL (Figure 3). The species is found principally on healthy skin, or mixed with other species such as *M. furfur*, *M. sympodialis*, *M. globosa*, or *M. restricta*, but always at a lower frequency. It is unlikely to be a major pathogen, at least on humans.

Maintenance of *Malassezia* in collections

Several reasons explain why the taxonomy of the genus *Malassezia* remained for so long a matter of controversy. Primarily, the lipophilicity was not understood and for years the different entities were known only from the literature, without any material deposited in fungal collections. When cultural isolation became possible,

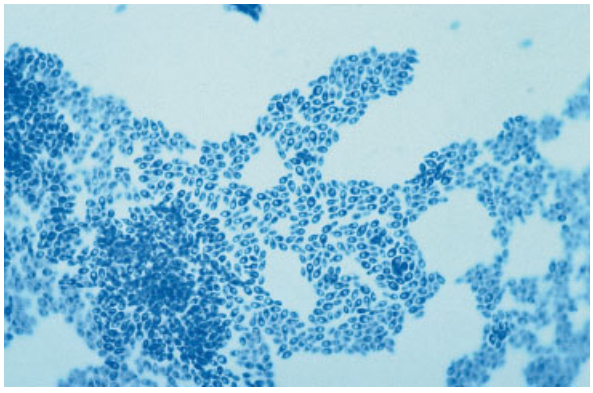

Figure 13 *Yeast cells of* M. restricta. *Lactophenol Cotton Blue, ×1 000*

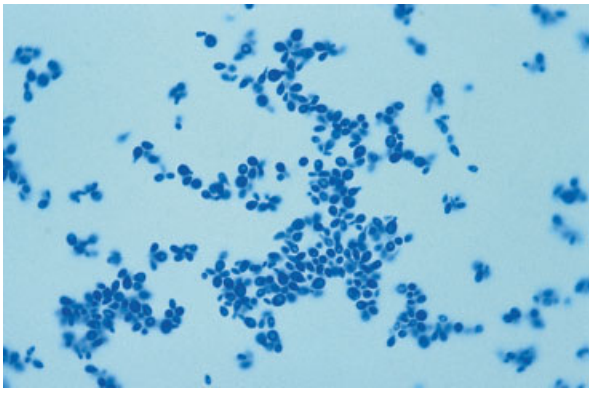

Figure 15 *Cylindrical yeast cells of* M. slooffiae. *Lactophenol cotton blue, ×1 000*

isolates started to be deposited. However, with time, only the less demanding species, essentially *M. furfur* and *M. pachydermatis*, have survived. In 1989, Guého and Meyer published the reevaluation of the genus *Malassezia*, based for the first time on genome comparisons but using lyophilized strains or strains maintained for years in the Dutch CBS fungal collection (Centralbureau voor Schimmelcultures). Furthermore, the lipid-dependent strains were grown on olive-oil-supplemented medium. The authors limited, as described by Yarrow and Ahearn (1984), the genus to only two species. In fact, only *M. furfur*, *M. pachydermatis*, *M. sympodialis*, and *M. slooffiae* survive lyophilization. For successful taxonomic revision (Guého et al. 1996), the work compared strains maintained in collections housing a large number of fresh isolates. All cultures were performed on mDixon which allows a better maintenance of all species. They are also never incubated or preserved at room temperature, but at 34°C with transfers every few months. Indeed, at room temperature, even with *M. pachydermatis*, losses are significant. The collection was then preserved in parallel with mDixon freeze-dried cultures, stored at –80°C. Crespo et al. (2000c) confirmed the importance of storage conditions used to preserve *Malassezia* yeasts.

ECOLOGY OF *MALASSEZIA* SPP.

The *Malassezia* yeasts have an absolute requirement for lipids to grow and survive. Furthermore, they are mesophilic, in other words their optimal temperature of life is between 30 and 35°C. These two physiological peculiarities explain why they are known only from the skin of warm-blooded animals. In the laboratory they can be obtained and maintained in culture only if specific nutrients and growth temperature are provided. Veterinarians have investigated the role of *M. pachydermatis* in causing ear infections in dogs for a long time (Guillot et al. 1998; Guillot and Bond 1999). Recently, some cases have been reported where *M. furfur* and *M. obtusa* were isolated as agents of otitis externa in dogs, and *M. sympodialis* in a similar condition in cats (Crespo et al. 1999, 2000a, b). Many studies had already demonstrated that *Malassezia* lipid-dependent spp. also colonize the skin of many other animals: monkeys, pigs, rhinoceros, bears, and birds (Midgley and Clayton 1969; Dufait 1985; Guillot et al. 1994, 1998).

The presence of *Malassezia* spp. in healthy human skin had been detected in earlier work during the second half of the nineteenth century. The frequency and density of colonization are related to the subject age and to sebaceous gland activity in the studied area (Marcon and Powell 1992).

Since the new descriptions, some studies have focused on their precise distribution in normal human skin. Crespo Erchiga et al. (1999a, b, 2002) with three successive studies made up of nearly 300 adults, showed that *M. sympodialis* appears as the predominant species in healthy skin, especially of the trunk, where it can be recovered in great numbers from more than 50 percent of individuals. It can also be found on the face, though at a lower percentage, together with *M. globosa*. This latter species can be found alone in about 10 percent of subjects. In a new ongoing study by the same authors (unpublished data), *M. restricta* seems to be predominant in the scalp, where it is isolated in 20 percent of adults, though always associated with a certain degree of scaling. Aspiroz et al. (1999) also found *M. restricta* associated particularly with the scalp skin, *M. sympodialis* with the back, while *M. globosa* was evenly distributed on scalp, forehead, and trunk. These data are similar to those published by Midgley in the UK in 2000, although this author reports a higher percentage of *M. globosa* in the scalp (45–50 percent). In these different surveys, the number of *M. furfur sensu stricto* isolates is very low (Midgley 2000; Crespo Erchiga et al. 2002), and even absent (Aspiroz et al. 1999).

In a Japanese study of 35 normal subjects, only *M. globosa* (51 percent) and *M. sympodialis* (26 percent) were recovered from the trunk. Sixty percent of scalp and face samples remained negative in culture, whereas *M. globosa*, *M. furfur*, and *M. sympodialis* were isolated from a few cases (Nakabayashi et al. 2000). In Russia, *M. sympodialis* was found to be the most common species in the skin of 32 healthy individuals, whilst *M. globosa* was encountered much less frequently (Arzumanyan 2001). In Canada, *M. sympodialis* was also the commonest species in 20 healthy control subjects (Gupta et al. 2001a). In this study, *M. globosa* was equally recovered from the scalp, forehead, and trunk, but less from the arms and legs, whereas *M. restricta* and *M. slooffiae* were recovered more frequently from the scalp and forehead than from the lower body. Differences encountered among these various studies may be explained by the different sampling techniques, culture media (Leeming-Notman by Gupta et al. 2001a, and mDixon by Midgley 2000, Nakabayashi 2002 and Crespo Erchiga et al. 2002), and possibly also by ethnic and geographical factors.

Finally, Sugita et al. in 2001, using a nested polymerase chain reaction (PCR) technique, detected *Malassezia* DNA in 78 percent of the scalp and nape samples of 18 healthy subjects. Among these isolates, *M. restricta*, *M. sympodialis*, *M. globosa*, and *M. furfur* were found at frequencies ranging from 61 to 11 percent. These results confirm that at least four *Malassezia* species, *M. sympodialis*, *M. restricta*, *M. globosa*, and *M. furfur*, are common inhabitants of the human skin.

SUPERFICIAL DISEASES ASSOCIATED WITH *MALASSEZIA* SPP.

The yeasts of the genus *Malassezia* are associated in a variable way with a number of human diseases, basically

affecting the skin, although in the last two decades a number of opportunistic systemic infections, most in premature neonates and related to the administration of lipids through intravenous catheters, have been described (Mickelsen et al. 1988; Midgley 2000; Crespo Erchiga and Delgado 2002).

Pityriasis versicolor

Pityriasis versicolor (PV) is a chronic, benign cutaneous disorder, usually asymptomatic, and characterized by slightly scaly patches of variable color (either pink, brown, or white) localized in the upper trunk. It has a worldwide distribution, though it is more frequent in tropical climates, where it has been reported in 30–40 percent of the population. The incidence in temperate climates is much lower (1–4 percent). It affects mainly young adults of both sexes although in tropical zones it is also very common in infancy and even in babies. The onset of the disease seems to be related mainly to local factors such as high temperature and humidity. The appearance on the trunk in the classic form of PV is probably related to occlusion produced by clothing. The condition appears generally in otherwise healthy people, and its incidence is not higher in those with acquired immunodeficiency syndrome (AIDS).

The diagnosis is usually performed by direct observation of the typical yeast and pseudo-hyphae features present in PV skin scales, using the reactive KOH-Parker ink (Figure 16). The yeasts are spherical, as are those of *M. globosa*, in the majority of cases, and occasionally oval, as are those of *M. furfur*. Indeed, in the taxonomic revision, it appeared that only *M. globosa* and *M. furfur* were able to filament more or less spontaneously (Guého et al. 1996).

Historically, Gordon was the first to assume that the rounded forms of *Malassezia* yeasts, he referred to *P. orbiculare*, were the etiologic agents of PV (Gordon 1951a, b). Following the description of new taxa, a few epidemiologic studies have dealt with this question.

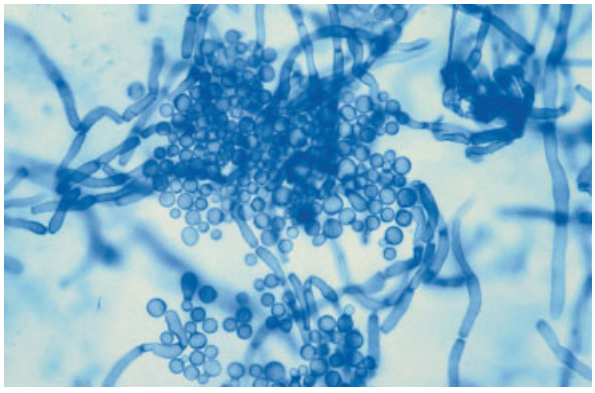

Figure 16 *Typical globose yeasts and pseudohyphae in PV skin scales. KOH+Parker ink, ×1000*

In Japan, Nakabayashi et al. (2000) found *M. globosa* present in 55 percent of PV scale samples of 22 patients, whilst all other species were below 10 percent. They suggested that this species plays a pathogenic role in the disease, as proposed previously by Crespo Erchiga et al. (1999a).

In a study carried out in Canada, Gupta et al. (2001b) found *M. sympodialis* (59 percent), *M. globosa* (25 percent), and *M. furfur* (11 percent) in 111 PV cases. In this study, a high number of cases with positive microscopy failed to grow in culture, and the authors suggested that this was consistent with the standard sampling practice of scraping the older (central) parts of PV lesions rather than the margins.

In Southern Spain, Crespo Erchiga et al. (2000) performed three successive epidemiologic studies, comparing the isolation of *Malassezia* spp. from PV, seborrheic dermatitis, and healthy skin from the same patients, with normal subjects. In the lesions, direct microscopy always showed the typical mixture of globose yeasts and filaments. As a result of this study, the authors did not find that the central parts of clinical lesion were less suitable for culture than margins. In contrast to other dermatomycoses (such as tinea), *Malassezia* yeasts and pseudomycelium can be distributed in similar amounts all over the affected skin, while scraping margins could lead to a higher recovery of surrounding commensal species, such as *M. sympodialis*. In the last group of this survey, consisting of 96 adult patients, *M. globosa* was isolated from 97 percent of cases, alone in 60 percent of them, and associated with *M. sympodialis* in 29 percent, or *M. slooffiae* in 7 percent. These two species were also found in similar percentages in the clinically uninvolved skin of the trunk, whereas *M. globosa* was not isolated at these sites. However, on the forehead, a small number of *M. globosa* colonies were recovered in 12 percent of cases. The presence of this species, in its yeast phase, in seborrheic dermatitis and healthy skin, indicates that local factors (humidity, sweat, heat, and seborrhea), together with some degree of idiosyncratic individual predisposition are responsible for the transformation to the mycelial form and the development of clinical lesions. In 2002, Crespo Erchiga et al. presented new results obtained with a case study of 210 PV patients. These new results were consistent with previously published data that thus confirmed the role of *M. globosa* in the etiology of PV, at least in the clinical form seen in temperate climates.

Three other studies support this conclusion. In Spain (Zaragoza), Aspiroz et al. (2002), with a survey of 79 PV patients, recovered *M. globosa* in 90% and *M. sympodialis* in 41 percent. In Japan, Nakabayashi (2002), using PCR identification of *Malassezia* species involved in PV, found *M. globosa* (97 percent) as the most commonly detected species, followed by *M. restricta* (79 percent) and *M. sympodialis* (68 percent). Finally, in Greece,

Gaitanis et al. (2002), using a DNA-PCR procedure, directly applicable to pathological skin scales, detected and identified only *M. globosa* from PV scales, an identification also confirmed by positive culture and biochemical tests.

An interesting point, already discussed by earlier authors, is whether the species associated with PV can vary depending on clinical and geographical distribution. Ingham and Cunningham in 1993 affirmed that this discussion had started at the beginning of the century. Castellani (1925), for instance, thought that pityriasis seen in tropical zones was a separate entity, and Panja (1927) divided the disorder into two diseases, named pityriasis versicolor (due to *M. furfur*) and pityriasis flava (due to *M. tropica*). In temperate zones, lesions affect the upper trunk principally and, although there are variations under direct microscopy, they regularly show globose cells. In tropical regions, by contrast, lesions preferentially affect the face and limbs and oval or cylindrical cells are found. Midgley (2000) concluded that the species responsible for PV could vary with the body site and different regions of the globe. According to Crespo Erchiga's experience, only 1 percent of PV cases displays, under direct scale examination, oval or cylindrical yeasts (Figure 17). The lesions showing this kind of picture are usually of an atypical distribution, affecting the face or limbs, and seem to be found mostly in patients from tropical regions. In Guého's experience, the number of PV cases for which the responsibility of *M. furfur* can be proved increases significantly when material taken from lesions of PV is incubated at 37°C (Guého and Meyer 1989). Indeed, *M. furfur* is a regular skin inhabitant and this species is responsible for all deep infections due to a lipid-dependent *Malassezia* species whatever the geographical origin of the patient (Boekhout et al. 1998; Theelen et al. 2001). However, this species has been unexpectedly rare in most recent investigations using either the Dixon or Leeming and Notman media. *M. furfur* may also be considered to be a regular but sparsely distributed inhabitant of human skin, taking advantage of an ecological niche only when the other species are eliminated or not present.

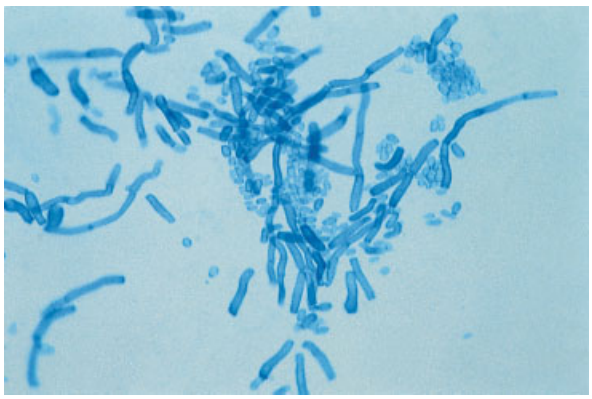

Figure 17 *Atypical oval yeasts and pseudohyphae in PV scales. The patient was a child with hypochromic lesions on the face. KOH+Parker ink, ×1 000*

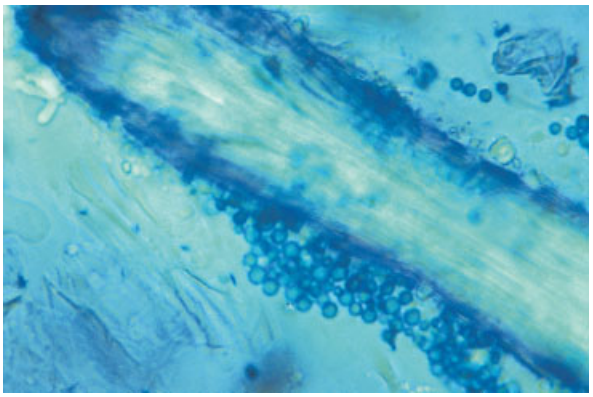

Figure 18 *Direct microscopy of PV scales, with* M. globosa *yeasts surrounding a villous hair and penetrating the follicle. KOH+Parker ink, ×1 000*

The immunological responses of PV patients to *Malassezia* yeasts have been investigated with equivocal results. Wu and Chen (1985) found an increase in humoral *Malassezia* antibodies in patients, compared to control subjects, while other studies did not find any difference between the two groups (Faergemann 1983; Midgley and Hay 1988; Ashbee et al. 1994a). Conflicting results have also been documented in investigations of cellular immunity.

The treatment of PV is simple, with rapid disappearance of lesions after treatment with different antifungal drugs, given either orally or topically, although the achromic areas can persist for weeks and even months. Topically, the most common substances used are selenium sulfide, propyleneglycol, and antifungal azoles. In extensive cases, the short-term use of systemic drugs, such as ketoconazole or itraconazole, is recommended. However, in spite of good initial results, the rates of recurrence after treatment are very high, about 60 percent after 1 year and 80 percent after 2 years, probably because underlying conditions and local factors remain unmodified. The maintenance of yeasts in the deep portions of the pilosebaceous follicles, frequently observed in KOH (Figure 18), may also explain such a high rate of recurrence. Prophylactic itraconazole treatment, 200 mg 1 day per month for 6 consecutive months, showed mycological cures in 88 percent of cases at the end point (Faergemann et al. 2002).

Seborrheic dermatitis

Seborrheic dermatitis (SD) is a chronic, relapsing skin disorder, characterized by the appearance of greasy, scaly, reddish patches localized in sebum-rich areas, such as the scalp, eyebrows, paranasal and middle thoracic

regions. Dandruff, which affects 5–10 percent of the adult population, is considered to be the mildest or initial form of the disease. AIDS patients have an increased incidence of SD, suggesting that the immune system plays an important role in the pathogenesis of the disease. The incidence is also higher in patients with neurological disorders such as Parkinson's disease, multiple sclerosis, and mood depression. The rare cases of *Malassezia* blepharitis can also be related to this skin disorder (Thygeson and Vaughan 1954; Ninomiya et al. 2002).

The relationship between *Malassezia* yeasts and SD is still a matter of controversy. Sabouraud (1932), during the first half of the past century, considered the yeast *Pityrosporum malassezii* to be the causative agent of the disease. In a critical review of the literature, Shuster (1984) described *P. ovale* as the etiologic agent. Since then, numerous studies have shown that a relationship exists between the severity of SD and the density of *Malassezia* cells present in dandruff. The taxonomic revision has generated several studies, aimed at tracing the different distribution of species in SD lesions. In Japan, Nakabayashi et al. (2000) isolated *M. furfur* (35 percent) and *M. globosa* (22 percent) from SD facial lesions of 42 patients, and less from normal subjects. In Canada, during a study using contact plates from 28 SD patients, Gupta et al. (2001a), found decreasing proportions of *M. globosa*, *M. sympodialis*, and *M. slooffiae*. In Spain, Crespo Erchiga et al. (1999a) concluded, in a survey of 75 SD patients, that *M. restricta* (43 percent) and *M. globosa* (34 percent) were the predominant species on the scalp and face of SD patients. Indeed, *M. sympodialis* (19 percent), *M. slooffiae* (2.5 percent), and *M. furfur* (0.8 percent) were much less prominent in this clinical feature. In more than 50 percent of lesional skin specimens, more than one species was obtained in culture. By contrast, healthy skin of the same area (forehead) remained sterile in 90 percent of samples, whereas 62 percent of the healthy trunk skin (shoulders) of the same patients yielded *M. sympodialis* predominantly. This striking difference might, of course, reflect the use of shampoos containing antifungal additives.

Crespo Erchiga and Delgado Florencio (2002) in a new study of 100 SD patients confirmed that *M. restricta* (65 percent) and *M. globosa* (64 percent) were the predominant species in SD lesions, followed by *M. sympodialis* (27 percent), mainly in lesions located on the trunk, and *M. furfur* (4 percent). In the healthy skin of the forehead, *M. sympodialis* was found in 20 percent of patients and *M. globosa* in 10 percent, whilst on the shoulders *M. sympodialis* was present in 58 percent of individuals and *M. globosa* in 7 percent. The same year, Gemmer et al. in the USA (Cincinnati), in a survey of 70 subjects with SD, using a direct fluorescent nested rDNA PCR of scalp samples, demonstrated that *M. restricta* (50–72 percent, depending on the flaking levels) and *M. globosa* (33–45 percent) were the predominant species in dandruff, whilst *M. sympodialis* was detected in a very small percentage (7–8 percent), and *M. furfur* not at all.

The increased incidence of SD in inmunosuppressed patients suggests that immune mechanisms are important in the pathogenesis of this disease. Both cellular and humoral immune responses have been investigated with conflicting results. Some studies of humoral *Malassezia* antibodies, compared with normal subjects, have shown increased titres in patients (Ashbee et al. 1994b; Silva et al. 1997a), whereas another did not show significant differences (Parry and Sharpe 1998). Lately, Midgley (2000) has shown that 72.5 percent of SD patients and 32 percent of PV patients had precipitating antibodies against *M. globosa*, in contrast to only 20 percent of normal control subjects. The results of testing cellular immunity are also contradictory. Meuber et al. (1996) found a reduced lymphocyte stimulation reaction when SD patients' cells were stimulated with *P. ovale* extract. By contrast, Ashbee et al. (1994b) showed an increase in both lymphocyte transformation responses and leukocyte migration inhibition. Faergemann et al. (2001) have reported increased numbers of NK1+ and CD16+ cells and in complement staining that suggest that an irritant nonimmunogenic stimulation of the immune system is important in the pathogenesis of the disease. The results of interleukin (IL) assays (increase in the production of inflammatory IL and in the regulatory IL for both Th1 and Th2 cells) showed similarities to the immune response described for *Candida* infections.

Kesavan et al. (2000) compared the inmunomodulatory capacity of normal and lipid-depleted *Malassezia* yeasts (using *M. sympodialis*, *M. globosa*, and *M. restricta*). They demonstrated that the extraction of lipids reversed their capacity to reduce the levels of proinflammatory cytokines. The lipid microfibrillar layer of *Malassezia* cells may prevent them from inducing inflammation and explain their normal commensal status on human skin. The absence or alteration of this lipid layer may provide an explanation for the inflammatory nature of the lesions.

Treatment options include selenium sulfide-, pyrithione zinc-, piroctone olamine-, or ketoconazole-containing shampoos, topical terbinafine solution or ketoconazole cream as well as topical corticosteroids. The corticosteroids, even the mildest ones such as hydrocortisone acetate, provide a rapid improvement of skin and scalp lesions, and relapse may be delayed by combining corticosteroids with ketoconazole. These favorable treatment responses suggest that *Malassezia* yeasts, especially *M. restricta* and *M. globosa*, are important in the etiology of SD and dandruff.

This skin disorder is also known from animals. Historically, the species *M. pachydermatis* was isolated from an exfoliative dermatitis of an Indian rhinoceros (Weidman 1925), and now the species is regularly

reported to cause SD in various animals, dogs and cats particularly, possibly because pets are more often investigated than other animals (Guillot et al. 1998; Guillot and Bond 1999). Bond and Lloyd (2002) compared IgG responses of various healthy and infected dogs, using Western immunoblotting. They found differences in the immunoreactivity according to the type of dog.

Atopic dermatitis

Atopic dermatitis (AD), or atopic eczema, is a common chronic inflammatory skin disease of unknown etiology. Clemmensen and Hjorth suggested for the first time in 1983 a role for *Malassezia* yeasts in this disease. Furthermore, they found a significant effect of oral ketoconazole in the treatment of adult patients with eczematous lesions on the head and neck. Since then, many reports highlighted the importance of such yeasts in AD. Faergemann has published comprehensive reviews of this disorder (Faergemann 1999, 2002). He concluded that *Malassezia* yeasts may play a major role as allergens in some patients, especially those with a head and neck eczema distribution, and suggested that treatment of such cases should include antifungal therapy. Tengvall Linder et al. (2000) found *P. orbiculare*-specific IgE in serum from 13/15 AD patients, and a positive patch test reaction in 8 of them, whereas SD patients and healthy controls were radioallergoabsorbent test (RAST) and patch test negative. They concluded that *Malassezia* yeasts can trigger an eczematous reaction in sensitized patients. Devos and van der Valk in 2000 have also shown that *P. ovale*-specific IgE is strongly related to a head and neck AD localization. Koyama et al. (2000) have described a *M. globosa* glycoprotein, named Malg46b, as a possible major antigen for IgE antibodies in these patients. Using a nested PCR technique, Sugita et al. (2001) compared the cutaneous colonization by *Malassezia* species in AD patients and healthy subjects. *M. restricta* and *M. globosa* were detected in approximately 90 percent of the patients, and *M. sympodialis* and *M. furfur* in about 40 percent (species mixture in a certain number of cases). In control subjects, *M. restricta*, *M. sympodialis*, *M. globosa*, and *M. furfur* were isolated at a frequency ranging from 61 to 11 percent. They concluded that the four species are common inhabitants of the skin of both AD patients and healthy subjects, but with an increased prevalence of *M. restricta* and *M. globosa* in AD patients. A new species, closely related to *M. sympodialis*, was isolated during this AD study from three patients, and was described as *Malassezia dermatis* by Sugita et al. (2002). However, its rarity excludes this species as being solely responsible for the disease. In 2003, Sugita et al., using the rRNA intergenic spacer (IGS) 1 region, divided *M. globosa* into four major groups and suggested that one of these genotypes may play a significant role in AD. Just after that, the same team (Sugita et al., 2003b) described *Malassezia japonica*, another new species that may be implicated in AD. This species is able to assimilate Tween 40 and Tween 60, but not Tween 20 and Tween 80; however, this is not clearly defined as yet.

Further studies are needed to clarify the inmunological as well as the mycological aspects of this dermatological condition, including a clear identification of etiologic species and of their antigens. Indeed, studies using *M. restricta* and *M. globosa*, the two major species recognized in AD, are still very rare (Koyama et al. 2000). When old names are cited, the connection of these organisms to the present species is not evident. *P. orbiculare* and *P. ovale* in such studies probably correspond to *M. sympodialis* in most cases (Mayser and Gross 2000), or to *M. furfur*.

Malassezia folliculitis

Mallassezia folliculitis (MF) is a benign disorder, characterized by follicular papules and pustules, localized predominantly on the back and chest. The condition is probably common, but often misdiagnosed as acne. The pruritus, associated with the absence of comedones and facial lesions, may facilitate the distinction between the two diseases. MF is more frequent in tropical countries, or during the summer in temperate regions. Occlusion seems to play an important role in this disorder, which has also been associated with antibiotic treatment (tetracyclines), corticosteroids, and immunosuppression (Alves et al. 2000). A minor epidemic outbreak has been reported in an intensive care unit (Archer-Dubon et al. 1999), and, during a 4-month period, 11 cases were described (out of 198 patients) in heart transplant recipients receiving immunosuppressive treatment (Rhie et al. 2000).

Direct microscopy and histopathology of pustules show the presence of abundant *Malassezia* yeasts in the pilosebaceous follicles. Back et al. (1985) observed round yeasts in most cases. At that time they identified yeasts obtained in culture as *P. orbiculare*. Such results suggest that *M. globosa*, as in PV, could be the predominant MF causative agent. Rhie et al. (2000) referred some of their cases as either being due to *M. furfur* or *M. pachydermatis*, but these authors did not apply the new *Malassezia* taxonomy. However, if hair follicle colonization by *Malassezia* yeasts is not abnormal, the diagnosis of MF is confirmed indirectly by the positive response to the antifungal therapy. Topical treatment may be effective in most cases, whilst others may respond to oral ketoconazole, itraconazole, or fluconazole.

Confluent and reticulate papillomatosis of Gougerot–Carteaud

The role of *Malassezia* yeasts in this rare cutaneous disorder, characterized by confluent hyperkeratotic papulae, grayish-brown pigmented, and located prefer-

entially on the trunk, is controversial. The diagnosis of confluent and reticulate papillomatosis of Gougerot–Carteaud (CRP), as that of MF, is based both on the observation (direct microscopy and histopathology) of lipophilic yeasts in the stratum corneum, and on a favorable response to topical or systemic antifungal treatments. In 1969, Roberts and Lachapelle suggested that CRP could represent a peculiar host reaction to heavy colonization by *P. orbiculare*. However, in the series revised by Nordby and Mitchell in 1986, only 5 of 19 patients responded to topical treatment with selenium sulfide. Other reports described complete recovery of CRP using retinoids (Baalbaki et al. 1993), minocycline (Shimizu and Han-Yaku 1997) or azithromycin (Raja Babu et al. 2000). Furthermore, two cases were also successfully treated with topical vitamin D analogs, either calcipotriol (Gülec and Seçkin 1999) or tacalcitol (Ginarte et al. 2002).

It is possible that this rare dermatological disorder represents more than one pathological condition, with *Malassezia* yeasts involved in only a few cases, perhaps those with a clinical pattern similar to that of PV. It could also be a basic disorder of keratinization, determined by an abnormal host response to *Malassezia* yeasts, or to bacteria or their products.

Neonatal *Malassezia* pustulosis

Since 1991, a few cases, characterized by non-follicular papulopustules located on face and neck of newborn infants, have been reported (Aractingi et al. 1991; Rapelanoro et al. 1996; Pont et al. 1998). The diagnosis, made in most of these cases by direct microscopy and histopathology, shows typical *Malassezia* yeasts. Moreover, the lesions cleared up after topical ketoconazole therapy. Rapelanoro et al. assumed that this condition could have been misdiagnosed as neonatal acne. Two more studies (Niamba et al. 1998; Bernier et al. 2002) have suggested that *M. sympodialis* could be the triggering agent for this rash.

Otitis

In 2000, a case of malignant otitis externa caused by *M. sympodialis* has been described in Australia (Chai et al. 2000). The patient, a man with a poorly controlled type II diabetes mellitus, had developed a severe infection, which started around the external auditory canal, and progressed with marked destruction of the temporal bone and an adjacent large soft tissue mass, below the skull base. The infection showed a total resolution after therapy with intravenous amphotericin B and fluconazole.

In animals, especially dogs, the role of the species *M. pachydermatis* in otitis is now well recognized by veterinary teams (Guillot et al. 1998; Guillot and Bond 1999; Crespo et al. 2000a, b).

Onychomycosis

A few onychomycosis cases, involving *Malassezia* spp., have been reported (Crozier and Wise 1993; Silva et al. 1997b; Escobar et al. 1999). However, the presence of *Malassezia* yeasts in nail material, a well-known though infrequent finding, is probably caused by subungual colonization by members of the cutaneous flora which makes the relevance of such cases uncertain. *Malassezia* yeasts have been observed occasionally in patients with distal fingernail onycholysis, associated with *Candida* spp. (Crespo Erchiga, personal observation). *M. furfur* was identified from an AIDS patient with an infected nail (Guého, unpublished result), and in a series of patients with onychomycosis in Brazil (Silva et al. 1997b). This species, which is also able to form hair nodules (Lopes et al. 1994, with identification confirmed afterwards by E. Guého), seems to be the only *Malassezia* species able to survive in such unusual conditions. The role of *Malassezia* yeasts in psoriasis (nails or scalp) is similarly questionable (Elewski 1990).

MOLECULAR METHODS OF IDENTIFICATION

The lipophilic yeasts of the genus *Malassezia* remained for years a complex and indeterminate group with a taxonomy based more on clinical and epidemiologic features than mycological characteristics, as demonstrated by the four former species *P. ovale*, *P. pachydermatis*, *P. orbiculare* and *P. canis*. The absence of a sexual cycle, appropriate classification of yeast morphology, and the absolute growth requirements for complex media were the reasons for this situation. Access to molecular methodology, in particular large subunit (LSU) ribosomal RNA sequencing, has led to a solution of these problems (Guillot and Guého 1995; Guého et al. 1996). Once the taxa were defined genetically, it was possible to define key characteristics applicable for routine use in any microbiological laboratory (Guého et al. 1998). However, such methodologies are time consuming (minimum 4 days after growth of cultures), and demand a high standard of practice in laboratory work. More and more laboratories are now equipped with PCR and are able to develop reproducible, precise and, above all, rapid molecular methods of identification. However, the molecular method must be chosen depending on the purpose of the study, either identification of species, typing of strains for epidemiologic surveys, or in vivo diagnosis from hosts. Indeed, the unique and ideal technique for every application does not exist as yet.

Species identification

RIBOSOMAL DNA (OR RNA) SEQUENCING

The taxonomic revision of the genus *Malassezia* was based on sequencing of the large subunit of ribosomal RNA D1/D2 domains which allowed investigators to define the seven species (Guillot and Guého 1995; Guého et al. 1996). These papers showed that this variable rRNA was a good alternative to nuclear DNA/DNA reassociation for yeast taxonomic work. Indeed, the former conventional characters of the nDNA guanine+cytosine content (GC %) and nDNA/DNA reassociation have now been used to validate each specific sequence. The DNA methodology, which is time consuming and fastidious yet still does not provide sufficient information, has now been abandoned in favor of rRNA or rDNA sequencing. Because most yeast mycologists have adopted the same rDNA region, recognition of an unusual yeast is becoming comparatively easy. Furthermore, with a sequence library extending day after day, a new species may be instantly positioned among the other related species (Nell et al. 2002), and in the classification of the Fungi (Sugita et al. 2002). In common with these latter authors, other mycologists have completed LSU rDNA sequencing with the use of rDNA ITSs. However, at the species level, one must keep in mind that strains of the same species may display about a 1.0 percent sequence divergence in the rRNA or rDNA D1/D2 regions (Kurtzman and Blanz 1998), and even more with other regions (Makimura et al. 2000). However, in 1997, Guillot et al., using the former rRNA D1/D2 sequences, recognized within the sole species *M. pachydermatis* seven sequence types (sequevars), with up to a 2 percent base substitution, but they did not divide the species. By contrast Sugita et al. (2002) described a new species *M. dermatis* which differs from *M. sympodialis* by only a 1.2 percent base substitution in their 26S rDNA D1/D2 and internal transcribed spacer 1 (ITS1)/internal transcribed spacer 2 (ITS2) region sequences.

PCR-RESTRICTION ENDONUCLEASE ANALYSIS

PCR-restriction endonuclease analysis (REA) with PCR of the 26S rRDA sequence allows one to separate the seven species (Guillot et al. 2000). The PCR products are digested with only three restriction endonucleases, *Ban*I, *Hae*II, and *Msp*I, which generate a unique pattern for each species. Moreover, this technique is very cheap and rapid, and detects and characterizes mixtures of several species. Gupta et al. (2000) have also assayed a similar analysis but the patterns generated were useful in the identification of only five species out of seven.

PULSED FIELD GEL ELECTROPHORESIS

Pulsed field gel electrophoresis (PFGE) shows that all *Malassezia* species display different karyotypes that do not vary intraspecifically, except in *M. furfur* (Boekhout et al. 1998). Senczek et al. (1999) applied PFGE, coupled to phenotypic characteristics, successfully to identify 220 *Malassezia* isolates, mainly from dogs. However, this technique, which has confirmed the seven genetic *Malassezia* species, does not appear to be the best choice for rapid species identification.

Molecular typing of *Malassezia* species

RNA AND DNA SEQUENCES OF IGS1 AND ITS1 REGIONS

rRNA sequences of the IGS1 region allowed the characterization of four genotypes within the species *M. globosa* with short sequence repeats CT(n) and GT(n). The authors (Sugita et al. 2003a) suggested also that one of these genotypes could be related to AD.

DNA sequences of ITS1 region may be used to identify (see above) or type species. Makimura et al. in 2000 using ITS1 sequencing were able to separate the seven *Malassezia* species and to recognize 22 ITS1-identical, individual groups. Among the 46 clinical isolates, they identified only *M. furfur* (11 strains from PV, four from SD, and four from AD), *M. sympodialis* (seven from PV, three from SD, one from AD and 11 from healthy controls), and *M. slooffiae* (three from chronic otitis and two from healthy controls).

RESTRICTION FRAGMENT LENGTH POLYMORPHISM

Restriction fragment length polymorphism (RFLP) of nDNA detects more or less specific variability according to the choice of the region amplified and the restriction enzyme battery. This technique allows investigators to trace sources of *M. pachydermatis* in bloodstream infections. One isolate was correlated in this way to a nurse's pet dog (Chang et al. 1998).

RANDOM AMPLIFIED POLYMORPHIC DNA

Random amplified polymorphic DNA (RAPD) implies a genomic DNA PCR using oligonucleotides as primers. In contrast to specific sequences of an rRNA- or rDNA-determined region, the RAPD markers are amplified by using arbitrary sequences. Boekhout et al. (1998) applied this methodology to the genus *Malassezia*, and found genetic variations in all species, particularly with four out of the 20 decamer primers tested.

AMPLIFIED FRAGMENT LENGTH POLYMORPHISM

Amplified fragment length polymorphism (AFLP) is a powerful method for fingerprinting genomic DNA, as well as generating a large number of dominant markers for genotypic analysis (Mitchell and Xu 2003). The

technique, which combines the strategy of enzymatic digestion and, usually, two PCR steps, is able to generate numerous fragments, when varying the restriction enzymes and the selective primers. In addition, the fragments are stable and highly reproducible. Like RAPD markers, AFLP markers are amplified partly by arbitrary primers, but with greater reproducibility and fidelity. However, this sophisticated technique, which generates complex patterns, is more appropriate for solving an unusual epidemiologic question. Theelen et al. (2001) found better typing resolution of *Malassezia* yeasts, in particular within *M. furfur*, with AFLP than with RAPD. Using AFLP, the seven species were separated and four genotypes could be distinguished within *M. furfur*, the genotype four containing only isolates from deep human sources.

MULTILOCUS ENZYME ELECTROPHORESIS

Multilocus enzyme electrophoresis does not use PCR technology but is among the most cost-effective methods for investigating genetic variations within a species at the molecular level. It was applied to *M. pachydermatis* (Midreuil et al. 1999), which was confirmed to be genetically heterogeneous. A total of 27 electrophoretic types were identified that could be divided into five groups with different host specificity. Unfortunately, traces of lipids used to grow lipid-dependent species were present, a problem that could not be resolved in this study.

In vivo identification of *Malassezia* species

Malassezia yeasts, particularly *M. globosa* and *M. restricta*, have fastidious culture conditions and exceedingly different growth rates. These difficulties have stimulated investigators to devise molecular techniques that are able to recognize *Malassezia* species directly from hosts. In 2001, Sugita et al. proposed the first method. They examined variations in cutaneous colonization by *Malassezia* species in AD patients and healthy subjects. DNA was extracted directly from dressings and amplified in a nested PCR assay. The diversity of *Malassezia* species found in AD was greater than in healthy subjects. In 2002, two teams described similar methods. Gaitanis et al. extracted *Malassezia* DNA directly from pathological skin scales by single and nested PCR. These authors amplified the rDNA ITS genes and then analyzed the PCR products by the technique of RFLP. The same analyses were obtained from positive cultures obtained from the same site and identified using basic biochemical tests. They obtained a good correlation with the two approaches and recognized the seven species, which were present as single or multiple isolates in the same specimen. The second paper (Gemmer et al.) investigated only the scales of dandruff from two groups of subjects, differentiated by their rate of composite adherent scalp flaking scores. Their technique involved fluorescent nested PCR of ITSs, coupled to a terminal fragment length polymorphism analysis. In this work, *M. restricta* and *M. globosa* were found to be the predominant species present in both groups, while the authors eliminated *M. furfur* as the causal organism for dandruff in their patients.

HISTORY

Historically, Agostino Bassi (1835–36) was the first to elucidate the microbial nature of a deadly disease of silkworms (*Bombyx mori*). Through meticulous studies and animal experiments carried out over a period of 25 years, he established unequivocally that a mold, now known as *Beauveria bassiana*, was the cause of a devastating disease of the commercially valuable silkworm. This was the first microorganism to be recognized as causing disease, long before the classic work of Robert Koch and Louis Pasteur. The discovery that a fungus could cause dermatophytosis was probably made by Robert Remak, who observed unusual microscopic structures in favic lesions. According to Seeliger's (1985) historical account, Remak claimed that he did not at first recognize the structures he saw as being fungal. Instead, he credited this recognition to his mentor, Professor Johann L. Schönlein, who described the fungal etiology in 1839. Remak (1845) later, however, cultured the causal fungus, established that it was infectious, and described the etiologic agent, in the context of its attendant disease symptoms, as *Achorion schoenleinii*.

Although Remak has priority for the discovery of the first fungus causing human disease, the real founder of medical mycology, based on his discoveries from 1841 to 1844, was the Parisian physician, David Gruby (Gruby 1841a, b, 1843, 1844; Zakon and Benedek 1944). Unaware of the observations of Remak and Schönlein, Gruby described the clinical and microscopic features of the causal agent of favus, and established the contagious nature of the disease (Gruby 1841a, b). He also described ectothrix hair invasion in beards and scalp hair of other patients, and named the etiologic agent involved *Microsporum audouinii*. The generic name he established referred in its etymology to the small spores that surrounded the hair shaft (Gruby 1843). Gruby (1844) also described a fungus he saw causing endothrix hair invasion as *Herpes (Trichophyton) tonsurans*.

In the early 1890s, Raimond Sabouraud, a French dermatologist, convincingly established the 'plurality' of the ringworm fungi and integrated the mycological and clinical aspects of ringworm. Based on the advances made by his contemporaries in medicine and veterinary science, as well as on his personal observations, Sabouraud wrote and published his monumental *Les teignes* in 1910. He classified dermatophytes into four genera: *Achorion*, *Epidermophyton*, *Microsporum*, and *Trichophyton*. This taxonomy was based on the clinical aspects of the disease that they caused, combined with their cultural and microscopic characters.

Emmons (1934) modernized the taxonomic scheme of Sabouraud. He critically reviewed the myriad dermatophyte species that had been described by Sabouraud and later workers in the European school, and discarded genera and species based on extrinsic factors such as their clinical manifestations and the host from which they were isolated. In addition, he rejected the

attribution of undue taxonomic import to trivial and highly variable characters, such as colony texture, chlamydospores, nodular organs, pigmentation, racquet hyphae, and spiral appendages. He discarded the genus *Achorion* and redefined the remaining three anamorphic genera – *Epidermophyton*, *Microsporum*, and *Trichophyton* – based on conidial morphology and other relatively reliably formed microscopic structures. Two decades later, nutritional, physiological, and morphological studies (Georg 1952; Silva and Benham 1952; Benham 1953; Swartz and Georg 1955; Ajello and Georg 1957; Georg and Camp 1957; Padhye et al. 1980) simplified the identification of the dermatophytes and led to a reduction in the number of species recognized.

The discovery of the teleomorphs (sexual or perfect states) of *Trichophyton ajelloi*, *Trichophyton terrestre*, *Microsporum gypseum*, and *Microsporum nanum* (Dawson and Gentles 1961; Stockdale 1961), using the hair-bait technique (Vanbreuseghem 1952), led to rapid discoveries of the teleomorphs of several other dermatophyte species and related keratinophilic taxa. The successful oral treatment of experimental *Microsporum canis* infections in guinea pigs with griseofulvin, by Gentles in 1958, opened new doors to the therapy of the dermatophytoses, especially ringworm of the scalp.

ETIOLOGIC AGENTS

The dermatophytes are closely-related keratinophilic fungi causing dermatophytosis (ringworm or tinea) by virtue, in part, of their ability to degrade keratin and thus to invade the skin, hair, and nails. The three anamorphs (asexual, conidial or imperfect state) of genera *Epidermophyton*, *Microsporum*, and *Trichophyton* are recognized as belonging to the family *Arthrodermataceae* of the order Onygenales, a group also containing other human pathogens such as *Histoplasma capsulatum* and *Coccidioides immitis*. Formerly, these asexual states were placed in a separate group known as the Deuteromycota or Fungi Imperfecti, but molecular studies and official changes in the guidelines for fungal nomenclature have allowed the abandonment of this artificial taxonomic category.

The dermatophytes capable of reproducing sexually are considered to be members of the genus *Arthroderma* (Weitzman et al. 1986) in the family *Arthrodermataceae*. The currently recognized dermatophytes and related nonpathogenic dermatophytoids are listed in Table 1 along with the names of their corresponding teleomorphs.

Physiologically, the dermatophytes facilitate distinction with special growth media by virtue of their high tolerance for cycloheximide and their ability to use proteins as a sole carbon source, releasing excess ammonium ion in a way that causes the pH of protein-containing media to rise into the alkaline range.

Table 1 *Dermatophytes and their nonpathogenic relatives: teleomorph and anamorph states*

Teleomorph (sexual or perfect state)	Anamorph (asexual or imperfect state)
Arthroderma spp.	*Microsporum* and *Trichophyton* spp.
A. benhamiae	*T. mentagrophytes* complex in part
A. cajetani	*M. cookei*
A. fulvum	*M. fulvum*
A. grubyi	*M. vanbreuseghemii*
A. gypseum	*M. gypseum* complex in part
A. incurvatum	*M. gypseum* complex in part
A. otae	*M. canis*
A. obtusum	*M. nanum*
A. persicolor	*M. persicolor*
A. racemosum	*M. racemosum*
A. simii	*T. simii*
A. vanbreuseghemii	*T. mentagrophytes* complex in part

Relatively few other fungi except some closely-related nonpathogenic members of the *Arthrodermataceae* combine these attributes, and among those that do, e.g. some *Exophiala* species in the 'black yeast' family *Herpotrichiellaceae*, most do not resemble dermatophytes in culture.

Morphological identification of the dermatophytes today essentially follows the classification scheme of Emmons: it is predominantly based on the microscopic characters of the anamorph and on the macromorphology of the colony on Sabouraud's glucose (dextrose) agar (SGA). The addition of 1 percent yeast extract to SGA, or use of other media such as cornmeal glucose agar or potato glucose agar may be necessary to stimulate conidiation. In addition, nutritional and other physiological tests may be required for species identification, especially of the *Trichophyton* spp.

Colonies should be examined for the color of the surface and underside, presence of diffusible pigment, surface texture, topography, and rate of growth. With regard to microscopic morphology, the types of conidia present, and their shapes and sizes, are essential criteria for identification; the presence of other structures such as pectinate (comb-like), coiled or antler-like hyphae, reflexive branches, chlamydospores or nodular organs may be helpful.

Many dermatophytes, especially those primarily associated with nonhuman hosts, regularly produce two kinds of conidia, large multicellular macroconidia and smaller unicellular microconidia. The presence or absence of these conidial types and the appearance of the walls of macroconidia (rough or smooth) are of generic significance. Species identification is largely based on the morphology and arrangement of the conidia.

Epidermophyton (Sabouraud 1907)

This genus is characterized by the presence of numerous, broadly clavate, nearly smooth-walled macroconidia; microconidia are absent. There is only a single recognized species, *E. floccosum*. It is anthropophilic, that is, specifically adapted to cause ongoing human infection. This species attacks skin, nails, and, very rarely, hair (Sherna et al. 1993).

Microsporum (Gruby 1843)

Members of this genus usually produce both macroconidia and microconidia. The essential distinguishing feature is the presence of macroconidia that have rough walls, with textures ranging from spiny to warty. The macroconidia vary in shape from egg-shaped (obovate) to cylindrofusiform; they may have thin to thick cell walls and 1–15 septa depending upon the species. The roughness of the cell walls may not be readily apparent in some isolates or species, and may require special media to induce its formation (Kane et al. 1997). Similarly, special media may be required for conidial production. Microconidia are typically clavate (club-shaped). In microscopic examination, one should also note the formation and arrangement of both types of conidia. Members of this genus regularly attack skin and hair but only occasionally nails.

Trichophyton (Malmsten 1845)

Smooth-walled macroconidia and microconidia are produced by typical members of this genus. The macroconidia may range in shape from elongate to pencil-shaped, clavate, fusiform, or cylindrofusiform. They are multiseptate and may be thin or thick walled. Microconidia are usually produced in greater abundance than macroconidia and their shape varies from pyriform, clavate, spherical to elongate. They are borne along the hyphae singly or in clusters and are sessile or borne on short stalks. Their arrangement on fertile hyphae is one of the important factors in their identification. Members of this genus attack skin, hair, and nails. For many *Trichophyton* spp., special media may be required to stimulate conidial formation. Some species produce few or no conidia regardless of the growth conditions used.

Table 2 summarizes the essential features of the dermatophyte genera; Table 3 summarizes the recognized species, along with some nonpathogenic relatives, and Tables 4 and 5, (p. 7) present short synopses of the characteristic features of the species.

ECOLOGY

Dermatophytes have been grouped into geophilic, zoophilic and anthropophilic species based on the ecological niches in which they naturally occur. For pathogens, this classification is based on their host preferences as manifested at the population level (Georg 1960; Ajello 1962). That is to say, sporadic occurrences of pathogenic species on atypical hosts are ignored. Table 6, (p. 8) summarizes classification of dermatophyte species according to ecology and host preference.

Geophilic species

Geophilic species are considered ancestral to the pathogenic dermatophytes (Chemel 1980; Ozegovic 1980; Rippon 1988; Weitzman and Summerbell 1995). The natural habitat of these species is the soil, where they are associated with decomposing keratinous material, e.g. hair, feathers, horns, hooves, nails, etc. Carnivore dung predominantly containing animal hair is another prominent habitat; the inoculum presumably comes from underlying soil. Exposure to the soil is the main source of infection for humans and lower animals (Alsop and Prior 1961; Chemel and Buchvald 1970; Ajello 1974; Rippon 1985). Transmission of geophilic species from lower animals to humans or from human to human is rare. *M. gypseum*, one of the best examples of a geophilic dermatophyte, was reported as the causal agent of two unusual outbreaks in association with soil

Table 2 *Characteristics of the genera of the dermatophytes*

Genus	Macroconidia	Microconidia	Clinical
Microsporum	Rough walls; egg-shaped, fusiform; usually present and more numerous than microconidia	Usually present; pyriform or clavate; typically borne singly along the hypha	Members may attack skin, hair, rarely nails. *M. persicolor* does not invade hair
Trichophyton	Smooth-walled; pencil-shaped, clavate, fusiform to cylindrofusiform; often absent or less numerous than microconidia	Usually more numerous than macroconidia but may also be scarce or absent; clavate, pyriform or spherical, in clusters or singly along the hypha	Members may attack skin, hair or nails. *T. concentricum* does not attack hair
Epidermophyton	Smooth-walled; broadly clavate; singly or in banana-like clusters	Absent	Attacks skin and nails; generally does not invade hair

Table 3 *Dermatophytes and their nonpathogenic relatives: species of the genera* Epidermophyton, Microsporum, *and* Trichophyton

Epidermophyton	*Microsporum*	*Trichophyton*
E. floccosum	*M. audouinii*	*T. concentricum*
	M. canis	*T. equinum*
	M. cookei	*T. erinacei*
	M. ferrugineum	*T. interdigitale*
	M. fulvum	*T. megninii*
	M. gypseum	*T. mentagrophytes*
	M. gallinae	*T. rubrum*
	M. nanum	*T. schoenleinii*
	M. persicolor	*T. simii*
	M. praecox	*T. soudanense*
	M. racemosum	*T. tonsurans*
	M. vanbreuseghemii	*T. verrucosum*
		T. violaceum

(Alsop and Prior 1961; Rippon 1985). One such outbreak occurred in a cucumber greenhouse among workers handling soil enriched with horn and hoof fertilizer. Secondary infections occurred in children and adults in close contact with the infected greenhouse workers (Alsop and Prior 1961).

Zoophilic species

Zoophilic species have gradually evolved from soil to parasitize animals (Chemel 1980; Ozegovic 1980; Rippon 1988). They have lost their ability to survive over the long term in nonsterile soil, though their mating to form teleomorphic structures cannot occur on the host and must therefore occur on shed hairs of the host, along with other such keratinous materials, on soil. These fungi are primarily animal parasites or may be carried by apparently healthy, wild animals (Feurman et al. 1975; Chemel 1980; Ozegovic 1980; Pier et al. 1994). Human infections are acquired either by direct contact with an infected animal or indirectly by contact with fomites or other inanimate objects associated with keratinous material from the animal (Pier et al. 1994; Thomas et al. 1994; Weitzman and Summerbell 1995). Human infections by *M. canis*, an important zoophile, are usually acquired from cats and dogs (Rippon 1985; Pier et al. 1994).

Anthropophilic species

Anthropophilic dermatophyte species appear generally to have evolved from zoophilic species, although recent molecular studies indicate that *E. floccosum*, possibly derived from within the *M. gypseum* complex, may be an exception (Gräser et al. 2000a). Humans are the normal hosts for this group of species and transmission may occur by direct contact or indirectly by fomites (Weitzman and Summerbell 1995). Human-to-animal transmission of infection by an anthropophilic species is rare but has been documented in the literature (Kaplan and Gump 1958; Mayr 1989).

The evolution from saprobic life in soil to an almost exclusive existence as a colonizer of keratinized tissue of humans generally corresponds to a decrease or loss of conidial formation (Rippon 1985; Rippon 1988), as well as an inability to reproduce sexually (Rippon 1988; Tanaka et al. 1992; Summerbell 2002). This loss of sexual reproduction (Kwon-Chung and Bennett 1992) is observed in almost all of the anthropophilic dermatophytes, although a small number of apparently anthropophilic members of the *Trichophyton mentagrophytes* complex (isolates with velutinous morphology traditionally associated with the name *Trichophyton interdigitale*) retain the ability to mate as *Arthroderma benhamiae* or *Arthroderma vanbreuseghemii* in laboratory tests (Watanabe and Hironaga, 1981; Vasilyev and Bogomolova, 1985; Hejtmánek and Hejtmánkova 1989).

Certain zoophilic and anthropophilic species may represent an intermediate stage in the evolution of dermatophytes towards loss of the ability to reproduce sexually. *Arthroderma otae* (anamorph *M. canis*) exists predominantly as one mating type but is still capable of reproducing sexually when paired with the rare + mating type (Weitzman and Padhye 1978). Many anthropophilic and a few zoophilic species are apparently incapable of reproducing sexually but appear to exist exclusively as one mating type; they may be induced to form rudimentary sexual organs (abortive gymnothecia) when paired with appropriate tester strains of *Arthroderma simii* (Stockdale 1968; Young 1968; Kwon-Chung and Bennett 1992). An example of such a species is *Trichophyton rubrum*, which consists entirely of strains of (−) mating type.

In addition to a decrease or loss of conidial production and the ability to reproduce sexually, anthropophilic fungi generally tend to produce chronic infections that are less likely to resolve spontaneously (Rippon 1988). The distinction between a geophilic and zoophilic species may not always be obvious and may even be controversial. A typical geophilic species is *M. gypseum*. Its natural habitat is soil and it is not always associated with animals (Weitzman and Summerbell 1995). *M. gypseum* can be isolated readily from garden soil by using Vanbreuseghem's hair-baiting technique (Vanbreuseghem 1952). In addition, it can not only survive and flourish in the soil environment, but also propagates by producing numerous macroconidia in nature (Gordon 1953). It is also a common sporadic animal pathogen, and may cause limited outbreaks, but it is not known to cause enduring, chronic, directly transmissible infections in populations of any animal species. Although *M. nanum* causes ringworm mainly in pigs, its partially geophilic nature has been well established by its isolation from soil as well as by the demonstration that its characteristic macroconidia could be seen directly in soil suspensions (Ajello et al. 1964). If it

Table 4 *Characteristic of pathogenic* Epidermophyton *and* Microsporum *species in culture*

Species	Colony on SGA	Microscopic morphology	Key tests, features or comments
Epidermophyton floccosum	Surface olive, khaki or yellow-brown, flat or radially folded, white tufts with age; suede-like texture; reverse yellow-brown, slow growth rate	Numerous macroconidia, 20–40 × 6–8 μm; broadly clavate, 0–4 septa, single or in clusters	No microconidia
Microsporum audouinii	Surface white, gray or tan; flat or velvety; reverse salmon-pink or rust; moderate growth	Conidia few or absent; macroconidia bizarre, fusiform, elongated, thick, rough walled, septa irregular in intervals; microconidia clavate, borne singly along sides of hyphae, pectinate hyphae, terminal or intercalary chlamydospores	Brownish discoloration of rice grains and poor growth; does not perforate hair in vitro
M. canis (= *M. canis* var. *distortum*)	Surface white to buff, woolly, reverse yellow, orange to orange-brown; nonpigmented and dysgonic variants occur; growth rapid	Numerous macroconidia, fusiform with thick, rough walls, 18–125 × 5–25 μm, knobbed apex, up to 15 septa; few microconidia; in *M. canis* var. *distortum* many distorted thick, rough-walled macroconidia	Heavy sporulation on rice grains; perforates hair in vitro
M. cookei	Surface yellowish, reddish tan or lavender, powdery or granular; reverse deep wine-red; moderate growth	Numerous macroconidia, mostly ellipsoid, thick walled, some moderately thin walled resembling *M. gypseum*; abundant microconidia	Must be distinguished from *M. gypseum* and *M. racemosum*
M. ferrugineum	Surface yellowish to rust; heaped, folded, waxy; very slow growth	Irregular hyphae lacking conidia; coarse hyphae with prominent septa ('bamboo hyphae')	Does not perforate hair in vitro
M. gallinae	Surface white to pinkish, satiny, slightly folded; reverse strawberry red diffusible pigment; rapid growth	Macroconidia elongate, curved with blunt tips, smooth to slightly roughened at tips, 2–10 cells, 6–8 × 15–50 μm; microconidia present	Characteristic diffusible red pigment; does not perforate hair in vitro
M. gypseum complex (*M. gypseum*, *M. fulvum*)	Surface tan, rosy-buff, cinnamon, powdery to floccose; reverse buff or reddish brown; rapid growth	Numerous ellipsoidal to fusiform macroconidia, 25–60 × 7–15 μm, thin, rough walls; up to 6 septa; microconidia abundant	Differentiation of *M. gypseum* from *M. fulvum* by inducing the teleomorph on special media
M. nanum	Surface cream to tan; powdery; reverse reddish brown; moderate growth	Abundant ovoid or egg-shaped 1–3 celled macroconidia, 10–30 × 6–13 μm; microconidia rare to moderate	Colony resembles *M. gypseum* but with slower growth rate; macroconidia slightly resemble conidia of *Trichothecium roseum*
M. persicolor	Surface yellowish buff to peach; powdery or downy; reverse pink to reddish brown	Abundant spherical microconidia; usually in clusters, some clavate to pear-shaped; macroconidia clavate, smooth, thin walls, rough walls with age or on special media; spiral hyphae often present	Uncommon pathogen; perforates hair in vitro, growth at 37°C minimal; rosy colonies on peptone agar; no alkalinity on BCP milk solids glucose agar in contrast to similar-looking *T. mentagrophytes*
M. praecox	Surface pale yellow to yellow, powdery to velvety; pale yellow to orange on reverse; moderate growth	Abundant long, fusiform macroconidia, 40–90 × 7–17 μm, thin, smooth to spiny macroconidia, 2–8 septa; microconidia absent	Rare pathogen; does not perforate hair in vitro

(*Continued over*)

Table 4 *Characteristic of pathogenic* Epidermophyton and Microsporum species in culture (*Continued*)

Species	Colony on SGA	Microscopic morphology	Key tests, features or comments
M. racemosum	Surface beige-cream, granular; flat; wine red reverse; rapid growth	Abundant macroconidia, fusiform to ellipsoidal, 41–77 × 9–10 μm; resembles *M. gypseum*; numerous clavate, stalked microconidia in grape-like clusters (racemes)	Must be differentiated from *M. gypseum*, *M. cookei*; rare pathogen; perforates hair in vitro
M. vanbreuseghemii	Surface yellowish, cream or pink; powdery to downy; buff to pale yellow reverse	Numerous cylindrofusiform macroconidia, 44–87 × 11 μm; up to 12 septa, thick walls smooth to spiny; numerous microconidia	Rare pathogen; perforates hair in vitro

were a true geophile, however, it would be distributed in many environments lacking its specific animal population host, but this has never been demonstrated for *M. nanum*. Visualization of the characteristic macroconidia in the environment offers proof that a capability for saprobic existence has been retained, in that these characteristic conidia are not formed in infected animals or humans (Ajello 1974; De Vroey 1985). Summerbell (2002) has pointed out that the ability for sexual reproduction, a process that can only occur in the context of saprobic growth, can be correlated with numerous other characters indicating an alternatingly soil-borne and host-borne existence for most zoophilic dermatophytes.

Some mycologists consider *Microsporum persicolor* and *T. simii* to be geophilic (Padhye and Thirumalachar 1967; Matsumoto and Ajello 1987; Kwon-Chung and Bennett 1992), whereas others have treated them as zoophilic (Rippon 1988; Tanaka et al. 1992). Both species have been isolated repeatedly from soil and from the hair of apparently healthy animals harboring these fungi without any ringworm lesions (Gugnani et al. 1967; Contet-Audonneau and Percebois 1986). *M. persicolor* is most frequently isolated from rodents, notably bank voles (Ozegovic 1980) and can cause severe human infections (Rippon 1988). The isolation of *M. persicolor* from the cutaneous lesion of a woman and from her garden soil (both isolates being of the same mating type) (Contet-Audonneau and Percebois 1986) could be taken to suggest geophilism, though recent contact of infected voles with the garden in question can by no means be excluded. Similarly, *A. simii* (anamorph *T. simii*) causes sporadic ringworm in dogs, monkeys, poultry, and humans in India (Gugnani et al. 1967). Macroconidia associated with *M. persicolor* and *T. simii* have not been observed in the direct examination of soil samples.

EPIDEMIOLOGY

Species identification of the dermatophytes and knowledge of their host preference and ecology play an important role in epidemiology, public health issues, and infection control. Of special concern are those fungi capable of producing family or institutional outbreaks. Knowledge of the geographically endemic dermatophytes such as the African *Trichophyton soudanense* is also relevant to epidemiology, as it allows pinpointing exposure during travel, residence, or contact with a person from an endemic area. Geographical distribution will be covered elsewhere in this chapter (see Geographical distribution).

Geophilic fungi such as *M. gypseum* are usually transmitted from a soil source and can be secondarily transmitted by animals to humans (Kaplan et al. 1957).

Infections caused by *M. canis* can involve a variety of animals as hosts, but cats and dogs are the principal carriers (Rebell and Taplin 1974; De Vroey 1985; Rippon 1985, 1988; Kwon-Chung and Bennett 1992). Fomites play an important role in the acquisition of infections (De Vroey 1985; Thomas et al. 1994). Wakimoto et al. (1985) reported an outbreak of ringworm caused by *M. canis* in Japan involving a kitten, fomites, and person-to-person spread of the infection. However, institutional outbreaks of infections in adults in a chronic healthcare facility (Shah et al. 1988), and in neonates (Mossovitch et al. 1986; Snider et al. 1993), have been reported with no clearly demonstrated link to an infected animal. Transmission in these cases resulted from person-to-person spread and fomites. *Trichophyton verrucosum* and zoophilic forms of *T. mentagrophytes* are typically encountered in rural areas and are acquired by humans in these locations mostly from herd animals, usually cattle (Georg 1956, 1960; Rippon 1985). Tinea capitis and tinea corporis are the most common manifestations in children and tinea corporis, while tinea barbae occurs in adult males (Rippon 1985). Fomites play an important role in zoophile infections, as noted in an outbreak caused by the mouse dermatophyte, traditionally called *T. mentagrophytes* var. *quinckeanum* (Blank 1957; Georg 1960) but recently renamed *T. mentagrophytes sensu stricto* (i.e. 'in the strict sense of the name') (Gräser et al. 1999c). Granular varieties within the *T. mentagrophytes* complex, formerly referred to as *T. mentagrophytes* var. *mentagrophytes*, have rodent

Table 5 *Characteristics of common pathogenic* Trichophyton *species in culture*

Species	Colony on SGA	Microscopic morphology	Key tests, features, or comments
T. concentricum	Surface cream, amber or brown; heaped, folded; glabrous to velvety; very slow growth	Conidia absent, only sterile hyphae, antler-like hyphae lacking terminal swelling may be present	50% isolates stimulated by thiamine; geographically limited
T. equinum	Surface white, fluffy, dome shaped; becoming buff and folded; reverse lemon yellow to reddish brown, growth moderate	Abundant microconidia, variable, spherical, pyriform to elongated clavate forms, borne usually singly along hyphae, occasionally in small clumps; macroconidia rare, clavate, smooth walled	Requires nicotinic acid; autotrophic strains only known from Australia and New Zealand; some isolates perforate hair in vitro
T. erinacei	Surface white, powdery, flat; yellow pigment on reverse; rapid growth	Numerous clavate to pyriform microconidia borne singly along the hyphae and in regular clusters; macroconidia clavate to cylindrical, smooth, thin walled, rare	Perforates hair in vitro; urease test often slow
T. interdigitale anthropophilic subtype	White to cream-colored surface, downy to fluffy, reverse tan	Microconidia few, moderate or heavy, pyriform, singly along hyphae	Perforates hair in vitro
T. megninii	Surface pinkish, velvety; radial folding, reverse wine red; moderate growth rate	Abundant pyriform to clavate microconidia; macroconidia pencil-shaped, smooth, rare	Requires L-histidine; urease positive; in urea indole broth, may be negative in Christensen urea broth in 7 days
T. mentagrophytes complex, zoophilic types	Surface creamy tan to pink; powdery to granular, flat; reverse buff to red or reddish- brown; rapid growth	Abundant spherical microconidia in grape-like clusters; macroconidia smooth walled, clavate to pencil-shaped, spirals often present	No nutritional requirement; urease positive; perforates hair in vitro
T. rubrum	Surface typically white, velvety to fluffy, occasionally powdery to granular; reverse wine red, rarely yellow or brown diffusible pigment; moderate to slow growth; dysgenic, lavender heaped varieties rare	Microconidia scanty to numerous, pyriform borne singly along the hyphae; macroconidia rare in fluffy isolates, numerous pencil-shaped to clavate macroconidia in granular to powdery colonies, 15–30 × 4–6 μm	Urease negative except in some flat, heavily conidial isolates of the afro-asiatic variant, in vitro hair perforation negative
T. schoenleinii	Surface glabrous, waxy, heaped, cerebriform becoming velvety, white, gray to tan; very slow growth, cracks agar	Conidia usually absent; microconidia in old, velvety subcultures; antler-like hyphae (favic chandeliers) with swollen nail-head tips; chlamydospores and hyphal swellings frequent	Autotrophic for vitamins, equal growth at 25–37°C differentiates it from *T. verrucosum*
T. simii	Surface white, cream or buff; powdery, granular, flat; reverse straw to salmon; rapid growth	Abundant clavate to fusiform to cylindrical, thin-walled macroconidia, 30–80 × 6–11 μm, fragmenting or with intercalary chlamydospores; microconidia pyriform, clavate, singly along the hyphae, spirals may be present	Resembles *T. mentagrophytes* but produces an unusually high number of macroconidia in isolates that have been transferred several times
T. soudanense	Surface flat, yellow to wine red, with star-like margin in primary isolates	Macroconidia absent, microconidia clavate, scarce or absent; reflexive branches are seen along larger hyphae within radial striations	May or may not appear to have vitamin requirements

(*Continued over*)

Table 5 *Characteristics of common pathogenic* Trichophyton species in culture (*Continued*)

Species	Colony on SGA	Microscopic morphology	Key tests, features, or comments
T. tonsurans	Surface white, cream, pale yellow to sulphur yellow, tan, pink; powder, suede-like or velvety; flat or raised and folded; mahogany reddish-brown reverse; slow growth	Microconidia numerous, clavate or elongate, some swollen, variable in size and shape, borne singly along hyphae, often on relatively long, empty 'matchstick' stalks and often attached to open branched clusters of hyphae; macroconidia rare, cylindrical, smooth, thin walled, tips often bent on one side	Growth stimulated by thiamine; urease positive; in vitro hair perforation variable; major incitant of endothrix type of ringworm
T. verrucosum	Surface cream to tan, flat, velvety, discoid; white, heaped glabrous to downy; yellow-ochre, glabrous, convoluted; very slow growth	Conidia usually absent; microconidia clavate; macroconidia 'rat-tail', irregular; chlamydospores in chains characteristic ('string of pearls') best at 37°C	About 16% of isolates require thiamine and inositol; growth stimulated at 37°C (faster than at 25°C)
T. violaceum	Surface lavender to deep purple, glabrous, heaped, very slow growth; white glabrous variants may occur	Conidia typically absent except after extended cultivation on thiamine-rich medium; irregular hyphae and chlamydospores present	Growth and sporulation stimulated by thiamine

Gräser et al. (2000c) concluded that *T. megninii* is synonymous with *T. rubrum* and that *T. gourvilii*, *T. soudanense*, and *T. yaoundei* were synonymous with *T. violaceum*; Summerbell (2003), however, concluded that *T. megninii* was a distinct species and that *T. gourvilii* was a synonym of *T. soudanense*, while *T. yaoundei* was a synonym of *T. violaceum*.

or rabbit-family (lagomorph) population hosts, and inoculum from such sources have caused infections in numerous laboratory workers (Georg 1960; Hironaga et al. 1981; Sewell 1995). Zoophilic members of the *T. mentagrophytes* complex (including isolates mating as *A. benhamiae* as well as isolates mating as *A. vanbreuseghemii*) have been isolated from many mammalian species (Ozegovic 1980; Rippon 1985), but chronic population carriage is only known from rodents, lagomorphs, and hedgehogs to date.

Table 6 *Classification of dermatophytes based on ecology and host preference*

Geophilic	Zoophilic	Anthropophilic
M. cookei	*M. canis*	*E. floccosum*
M. gypseum complex	*M. gallinae*	*M. audouinii*
M. nanum	*T. equinum*	*M. ferrugineum*
M. persicolor[a]	*T. erinacei*	*T. concentricum*

M. racemosum	*T. verrucosum*	*T. megninii*
M. vanbreuseghemii		*T. rubrum*
T. simii[a]		*T. schoenleinii*
		T. soudanense
		T. tonsurans
		T. violaceum

a) Considered as zoophilic by Rippon (1988) and Weitzman and Summerbell (1995)

Some examples of less common infections contracted from other animals include *Microsporum gallinae* from fowl (Rippon 1985), *M. nanum* from pigs (Ajello et al. 1964; Morganti et al. 1976), *Trichophyton equinum* from horses (Georg et al. 1957; Zuckerman et al. 1992), *T. mentagrophytes* var. *quinckeanum* from mouse (Blank et al. 1961), *Trichophyton erinacei* (= *T. mentagrophytes* var. *erinacei*) from hedgehogs (Morris and English 1973; Philpot and Bowen 1992), *M. persicolor* from field voles (English et al. 1978; Onsberg 1978), and *T. simii* from poultry, dogs, and monkeys (Gugnani et al. 1967; Tewari 1969). Infections acquired from animals are usually inflammatory, but are more likely to resolve spontaneously than are infections caused by anthropophilic dermatophyte species (Rippon 1988; Kwon-Chung and Bennett 1992).

Infections caused by anthropophilic fungi are mostly acquired by direct contact with infected humans; fomites also play an important role and infection may even be acquired after aerosolization of infectious arthroconidia. *M. audouinii* and *T. tonsurans* have been isolated from the air (Friedman et al. 1960; Arnow et al. 1991) and several other dermatophyte species belonging to all three ecological groupings have been reported from house dust (Shimmura 1985). *M. audouinii* is an example of the extent of contagion and the potentially rapid spread of ectothrix tinea capitis. It was responsible for an epidemic in Europe in the nineteenth century that was later exported to North America and ended in the

mid-1950s (Rippon 1985). It was essentially eliminated by griseofulvin, but was replaced by a *T. tonsurans* epidemic that swept into the south and southwest of the USA and Canada, apparently derived from an ongoing epidemic in Puerto Rico and other Hispanic countries (Rippon 1985). Tinea capitis, in the form caused by *T. tonsurans*, is an endothrix type of scalp infection. It may persist subclinically in the scalp, resulting in long-term carriers who may shed viable propagules for decades (Weitzman and Summerbell 1995). In adults, it is more frequently manifested as tinea corporis and uncommonly as tinea manuum and tinea unguium (Weitzman and Summerbell 1995).

T. tonsurans has also been responsible for several institutional outbreaks (Mackenzie 1961; Kane et al. 1988; Arnow et al. 1991). One such outbreak of nosocomial tinea corporis occurred in a pediatric ward. The infection was spread by the index patient to the staff and a visitor. *T. tonsurans* was isolated from the air, soiled linen and the backs of chairs (Arnow et al. 1991). Another nosocomial outbreak was reported in a nursing home for elderly people and persisted for 9 months despite remedial and sanitary measures (Kane et al. 1988). The index patient, who was immobile, infected a staff member who, in turn, may have spread the infection to other immobile patients who in turn infected other staff. *T. tonsurans* was found in several environmental samples. A third outbreak occurred in a residential school for girls where clinical infections were found in 21 children, mostly as tinea capitis and less frequently as tinea corporis or tinea unguium (Mackenzie 1961). The fungus was isolated from such inanimate sites as the air, combs, brushes, bedding, floors, and a curtain. Tinea corporis among adolescents and young adults, caused by *T. tonsurans*, has been reported from contact sports such as wrestling (Stiller et al. 1992; Beller and Gessner 1994).

Tinea capitis is most commonly a dermatophytosis of childhood, as is tinea corporis caused by *M. canis*. Other forms of tinea are seen most commonly in adolescents and adults, and are most commonly caused by anthropophilic dermatophytes. Tinea cruris (groin), tinea pedis (feet), and tinea unguium (nails) are frequently caused by *T. rubrum*, *T. interdigitale* (a name recently redefined after molecular studies by Gräser et al. (1999c) and used here in its modern sense), and *E. floccosum*, although this may vary with geographical location. Fomites play an important role in transmission, but host factors such as immunological status and local factors such as trauma, excessive moisture or occlusive clothing may constitute risk factors when combined with exposure to the fungus.

Outbreaks of tinea cruris involving *T. rubrum* and *E. floccosum* have been attributed to sources of contagion such as toenail clippings, bedding, toilet seats, and saunas, as well as to exchange of clothing (Neves and Xavier 1964; Lundell 1974; Rippon 1988). Ringworm caused by other anthropophilic species such as *T. violaceum* and *T. schoenleinii* can be transmitted from person to person by clothing, cotton caps, pillows, combs, and towels (Padhye 1962; Kwon-Chung and Bennett 1992). Infection by *Trichophyton concentricum* is transmitted from mother to child after birth by contact (Rippon 1988), but fomites may also play a role in transmission (De Vroey 1985). Contagion either by direct contact or from fomites has been essentially established in tinea capitis, tinea corporis, and tinea barbae. With regard to tinea pedis, exogenous exposure to the fungus in showers, swimming pools, locker rooms, etc., plays an important role in the acquisition of clinical disease, though host susceptibility factors may also be involved (Gentles 1957; Gentles and Holmes 1957; Gip 1967; Zaias et al. 1996). Viable propagules of dermatophytes are shed from the feet of people with tinea pedis and these fungi have been isolated from areas where people walk bare footed and from towels, shoes, and socks (Ajello and Getz 1954; Gentles 1957; Gip 1967; Fujuhiro 1994). Epidemiological study showed a threefold increase of tinea pedis when communal showers were installed in a coal mine (Gentles and Holmes 1957).

The dermatophyte propagules most commonly associated with contagion in all anthropophilic dermatophyte infections and most zoophile infections are the substrate arthroconidia found within desquamated epithelium and hairs; these conidia can survive for an extended period of time in the environment (McPherson 1957; Mackenzie 1961; Kane et al. 1988; Rippon 1988; Kwon-Chung and Bennett 1992).

GEOGRAPHICAL DISTRIBUTION

The geographical distribution of the anthropophilic and zoophilic dermatophytes, rather than being static within a city, state, or country, is dynamic. It tends to be affected by periods of social change featuring changing immigration patterns, health habits, standards of living, or propensities for travel. For example, before 1900, tinea capitis was rare in North America, and was caused mostly by *M. canis* transmitted by animal contact (Rippon 1985). From 1900 to the mid-1950s a 'gray patch' ectothrix type of ringworm in children, caused by *M. audouinii*, spread over the USA and Canada. As mentioned above, this epidemic was in turn displaced by 'black dot' endothrix ringworm caused by *T. tonsurans* (Rippon 1985, 1992; Babel 1990), which was for the most part imported from Latin America and the Caribbean but went on to become the current predominant cause of tinea capitis in North America (Rippon 1985; Gupta and Summerbell 2000). *T. tonsurans* is now the second most commonly isolated dermatophyte in the USA; only *T. rubrum* is more common. *M. audouinii*, although still cultured sporadically, usually in connection with recent migrants from Africa, has virtually disappeared in the

USA (Sinski and Kelley 1991). In some southern European and middle eastern countries, *M. canis* is the most frequently isolated dermatophyte and threatens to become a serious epidemiological problem as a result of carriage by feral cats (Lunder and Lunder 1992). The geographical distribution of the geophilic, zoophilic, and anthropophilic dermatophytes is shown in Tables 7, 13.8 and 13.9. Dermatophytes endemic in certain geographical areas may be isolated outside such locations as a result of travel and immigration. *Trichophyton violaceum* (= *T. soudanense*), for example, which is widespread in Africa, has been reported among African immigrants in several European countries and in North America (Kwon-Chung and Bennett 1992; Viguie et al. 1992). For a more comprehensive review of the geographical distribution of the dermatophytes, readers should refer to publications by Ajello (1960); Sinski and Flouras (1984); Rippon (1988) and Kwon-Chung and Bennett (1992).

MOLECULAR TAXONOMY AND PHYLOGENETIC RELATIONSHIPS

In recent years, dermatophytes have been subject to extensive molecular systematic study. It has been confirmed that all sexual and asexual dermatophytes are, indeed, closely related to one another, and that all are members of the family *Arthrodermataceae*. (Anamorphic species and genera are now correctly said to belong to teleomorphic families in mycology when this information is unambiguously known, e.g. through molecular study.) Though further study is needed before firm conclusions can be drawn, it appears there may be four genera rather than three within the traditional grouping of dermatophytes and dermatophytoids. (The latter term refers to nonpathogenic species in genera containing dermatophytes.) The studies of Y. Gräser and colleagues (Gräser et al. 1999b, 2000a) have found that most of the nonpathogenic *Trichophyton* spp., e.g. *T. ajelloi* and *T. terrestre*, form a clade separate from the pathogenic species. *Microsporum* appears to be a distinct genus, but *Epidermophyton*, while supported as separate by some studies (Kano et al. 1999, 2002), is apparently contained within *Microsporum* in other studies (Gräser et al. 1999b, 2000a, b). Molecular mycologists tend to find it inconsistent to recognize the anamorphs in a clade as a separate genus, but not at the same time to recognize the generic status of the corresponding teleomorphs. Application of this viewpoint in the dermatophytes would tend to revive the generic name *Nannizzia* for teleomorphs in the *Microsporum* clade. No formal proposal to this effect, however, has yet been made.

At the species level, the separate status of all known sexual species within the dermatophytes has been upheld wherever studied. It has been found, however, that many asexual species appear to have arisen relatively recently in evolutionary time, and each of them except *E. floccosum* is closely related to a known sexual species. This has caused the validity of some species to be questioned. Numerous taxonomic challenges are posed by unusual population genetics patterns that can be seen within the asexual dermatophytes and their

Table 7 *Geographical distribution of geophilic dermatophytes*

Geophilic	Distribution
M. cookei	Cosmopolitan
M. gypseum and *M. fulvum*	Cosmopolitan
M. nanum	Cosmopolitan
M. persicolor	Cosmopolitan
M. praecox	Western Europe, North America
M. racemosum	Romania, Venezuela, USA
M. vanbreuseghemii	Russia, Africa, India, USA
T. simii	India

Table 8 *Geographical distribution of zoophilic dermatophytes*

Species	Geographical distribution in major animal hosts
M. canis	Cosmopolitan
M. canis var. *distortum*	Australia, New Zealand, USA
M. canis var. *equinum*	Africa, Australia, Europe, New Zealand, North and South America
M. gallinae	Cosmopolitan
T. equinum	Cosmopolitan
T. erinacei	Europe, New Zealand
T. mentagrophytes complex (zoophilic types)	Cosmopolitan; Australia, Canada, Eastern Europe, Italy
T. verrucosum	Cosmopolitan

Table 9 *Endemic geographical distribution of anthropophilic dermatophytes, excluding isolates in travelers and recent immigrants*

Species	Major geographical regions
E. floccosum	Cosmopolitan
M. audouinii	Parts of Africa
M. ferrugineum	Far East, West Africa, Eastern Europe
T. concentricum	Parts of Asia, Oceania, isolated areas inhabited by indigenous peoples in parts of Latin America
T. megninii	Portugal, Sardinia, Corsica, and parts of Africa
T. interdigitale	Cosmopolitan
T. rubrum	Cosmopolitan
T. schoenleinii	Parts of Africa and Asia
T. tonsurans	Cosmopolitan
T. violaceum	North and east Africa, west Asia

immediate sexual relatives. In some cases, sequencing studies have found interbreeding strains within a sexual species to be apparently more distantly related to one another than some of them are to certain morphologically and physiologically distinct asexual species. Moreover, in such cases, the genetically varied individual sexual species and the genetically restricted asexual species to which they appear to have given rise tend to infect different population hosts. For example, based on ribosomal internal transcribed spacer (ITS) sequencing, oligonucleotide polymerase chain reaction (PCR) typing, and amplified fragment length polymorphism (AFLP) typing, CBS 495.86, the feline-derived, (+) mating type, taxonomic cotype strain of *Arthroderma otae*, the teleomorph of *M. canis*, is more closely related to the anthropophilic, asexual species *M. audouinii* than it is to the (–) *A. otae* mating type strain, CBS 496.86, that serves as its complementary cotype (Gräser et al. 1999c). While it is not difficult to conceive that one clone of the (+) mating type of the cat dermatophyte may have transformed itself within a moderately short evolutionary time frame into a morphologically and physiologically distinct organism with a uniquely strong genetic adaptation for causing ectothrix infection of human preadolescent scalps, it is somewhat controversial to interpret this event as a speciation process. Sequences of noncoding and housekeeping parts of the genome, e.g. the ribosomal sequence and associated spacer regions, tend to have changed only slightly between at least some *A. otae*/*M. canis* strains and *M. audouinii*. At the same time, it is clear that in both interbreeding status and general population genetics, *M. canis* has a strong potential unity as a 'biological species,' and also has a common habitat leading to stabilizing selection of pathogenicity factors, morphology, and other aspects of phenotype. None of these factors is shared by *M. audouinii*, the connection of which to *M. canis* is purely historical. In view of this population genetics divergence, Summerbell (2002) has recently proposed recognizing *M. audouinii* and all other 'unifactorial asexual radiate lineages' within the dermatophytes, that is, all single-mating-type, asexual dermatophyte lineages that have undergone a population-host shift in respect to their most closely related sexual relative, as being distinct at the species level.

Some long-recognized asexual dermatophyte species have been formally proposed as synonymous with closely related species as a result of molecular phylogenetic studies. For example, *T. equinum* has been proposed as a synonym of *T. tonsurans* by Gräser et al. (1999c) based on ITS sequence and other molecular similarities. The rejection of this synonymy has subsequently been suggested, however, since the former dermatophyte, with equine population hosts, is of the (+) mating type, while the latter, with human hosts, is of the (–) mating type (Summerbell 2003). This evidence of long-term evolutionary separation was not acknowledged in the study originally proposing the synonymy of these species. Existing data suggest separate, though relatively evolutionarily recent, origins from a common ancestor rather than conspecificity for *T. equinum* and *T. tonsurans*.

Trichophyton gourvilii, *T. soudanense*, and *T. yaoundei* have been suggested to be synonyms of *T. violaceum* (Gräser et al. 2000c). Summerbell (2003), citing the apparently premature synonymization of *T. tonsurans* and *T. equinum* based on similar techniques, has called for additional confirmatory molecular genetic study before the morphologically and geographically distinct cluster containing *T. soudanense* and *T. gourvilii* is synonymized with *T. violaceum*.

Population genetics studies within other traditionally defined dermatophyte species have revealed highly divergent patterns. *T. rubrum*, for example, has been found to be characterized by a high degree of overall genetic uniformity suggestive of recent subclonal derivation from a preexisting clonal lineage that also gave rise to *T. violaceum* and *T. soudanense* (Gräser et al. 1999b, 2000c; Summerbell et al. 1999). *T. mentagrophytes*, on the other hand, has been found to subtend an unexpected degree of biodiversity. While it was long known to contain anamorphs of two biological species, *A. benhamiae* and *A. vanbreuseghemii*, and to be closely related to the *T. simii* anamorphs of *A. simii*, *T. mentagrophytes* as traditionally conceived by Emmons (1934) has recently been found also to phylogenetically encompass asexual radiates such as *T. schoenleinii*, *T. concentricum*, *T. verrucosum*, and the lineages giving rise to *T. equinum*, *T. tonsurans*, *T. soudanense*, *T. violaceum*, *T. megninii*, and *T. rubrum*. Gräser et al. (1999c) have proposed a formal nomenclatural neotypification that limits application of the name *T. mentagrophytes* to the group of isolates formerly referred to as *T. mentagrophytes* var. *quinckeanum*, the mouse favus dermatophyte. These isolates are capable of mating successfully with mating type testers of *A. benhamiae* (Weitzman and Padhye 1976); this teleomorphic species, however, is conceived as sufficiently phylogenetically distinct to be accepted as a taxon separate from *T. mentagrophytes sensu stricto* (Probst et al. 2002). This viewpoint is based on the common knowledge that in many biological groups, the ability to manifest interfertility under artificial conditions may be retained as a symplesiomorphic (inherited ancestral-type) character among closely related species that never interbreed in nature. The apparently clonal (Mochizuki et al. 1990, 1996) *T. mentagrophytes*-like lineage that is contagious among humans has been referred to a neotypified *T. interdigitale* (Gräser et al. 1999c). A few isolates compatible with this species retain an ability to mate with testers of the normally zoophilic *A. vanbreuseghemii*; the exact status of *A. vanbreuseghemii vis-à-vis T. interdigitale* is not yet settled. Certain other *T. mentagrophytes*-like lineages

that are capable of interbreeding, at least in vitro, with members of the established biological species, have also been conceived as separate species, e.g. the hedgehog dermatophyte, *T. erinacei*. In general, unraveling the complexity of these phylogenetic and tokogenetic relationships among dermatophyte lineages is a process that will require additional study.

CLINICAL FORMS

Infections caused by dermatophytes (ringworm, tineas) are clinically classified on the basis of the location of the lesions on the body. Although different body sites may be affected, each focus of infection is generally the result of local inoculation. The invading dermatophyte grows in a centrifugal manner, forming irregular rings with inflammatory borders with some clearing in the central area of the lesion. The name ringworm was based on the worm-like appearance of the lesions with irregular, inflammatory borders. The infection is named according to body site after the Latin word *tinea*. The word tinea itself comes from the clothes moth and the similarity of its effects on wool garments to the shape of the dermatophyte skin lesions (Ajello 1974). The clinical manifestations are classified as follows: tinea pedis (feet); tinea cruris (groin); tinea corporis (glabrous skin); tinea barbae (ringworm of the beard and moustache); tinea capitis (scalp, eyebrows, eyelashes); tinea manuum (hand); tinea unguium (nails); tinea favosa (favus); and tinea imbricate (ringworm caused by *T. concentricum*). The clinical manifestations and their major etiologic agents are described here briefly. More detailed information may be obtained by referring to texts by Rippon (1988); Kwon-Chung and Bennett (1992) and Kane et al. (1997).

Tinea pedis ('athlete's foot')

Ringworm of the feet involves infection of the interdigital webs and soles. The most common clinical manifestation is the intertriginous form associated with maceration, scaling, fissuring, and erythema, which presents with itching and burning. The other clinical form, which is commonly noted, involves a chronic, squamous, hyperkeratotic type of infection of the soles and heels extending up the sides of the foot (moccasin foot). This is an acute condition characterized by the formation of vesicles, and inflammation plus occasional pustules and bullae are most commonly caused by granular, zoophilic members of the *T. mentagrophytes* complex. The common agents of tinea pedis in cases of chronic infection are *E. floccosum*, *T. interdigitale*, and *T. rubrum*.

Tinea cruris ('jock itch')

This infection of the inguinal area involves the groin, perianal, and perineal areas, often involving the upper thighs. It is frequently caused in adults by *T. rubrum* and *E. floccosum*. Lesions are erythematous and scaly, exhibiting raised, inflamed borders often with vesicles. They are symptomatically associated with itching and burning. They are usually bilateral, extending down the inner thighs and over the proximal waist area and buttocks.

Tinea corporis

This ringworm of the upper parts of the body usually involves the shoulders, axilla, chest, and back. It may also involve the face, the legs, or the dorsa of hands or feet. The lesions are well marginated with raised erythematous, vesicular borders. The infection may be mild to severe. The annular, scaly patches may coalesce to form large areas of chronic infection when *T. rubrum* is the etiologic agent. Zoophilic dermatophytes frequently cause this infection.

Tinea barbae

This infection may be mild and superficial but, more often, the lesions are inflammatory and pustular, especially when caused by zoophilic dermatophytes such as *T. mentagrophytes* and *T. erinacei*. Erythematous patches are often scaly, and show lusterless hairs and folliculitis.

Tinea capitis

This ringworm involves infection of the scalp hairs and intervening skin. Infection may range from mild, with slight erythema and a few, patchy scaly areas, to severe, with inflammatory lesions involving folliculitis or kerion formation, often with secondary bacterial infection resulting in scarring and alopecia. Hair invasion occurs in two patterns, ectothrix and endothrix. In the ectothrix type of invasion, the invading fungus infects the hair shaft at mid-follicle and forms a sheath of hyphae and arthroconidia 2–3 μm in diameter surrounding the hair shaft. The infected hair become lusterless and brittle, and the hair filaments break off at the level of the scalp to give an appearance of partial alopecia. The best known agents of ectothrix scalp ringworm are *M. audouinii* (seen in Africa as a variant classically indicated by the synonymous name *M. langeronii*), *M. canis*, *M. ferrugineum*, and *M. gypseum*. *T. verrucosum* and *T.megninii* also occasionally cause ectothrix colonization of the hair shaft. In endothrix hair invasion, the hyphae invade the hair follicle and then grow into the hair shaft, forming numerous arthroconidia within it and severely damaging the hair in the process. The infected hairs become grayish-white and break off easily at the level of the scalp to give a 'black dot' appearance. The predominant cause of endothrix tinea capitis in the USA at

present is *T. tonsurans*. *T. violaceum* and *T. soudanense* are prevalent in other parts of the world. Lesions may coalesce to form large patches of alopecia.

Tinea manuum

This infection involves the palmar and interdigital areas of the hands. Lesions present as diffuse hyperkeratotic areas. Most infections are caused by *T. rubrum*.

Tinea unguium

Invasion of the nail plate by a dermatophyte is referred to as tinea unguium. Distal subungual infection is one of the common patterns of nail invasion and generally involves the nail bed and the underside of the distal portion of the nail. A mild inflammation produces hyperkeratosis and focal parakeratosis (Elewski et al. 1995). Subungual hyperkeratosis causes lifting of the nail plate and its detachment from the nail bed. *T. rubrum*, *T. interdigitale*, and *E. floccosum* are the main causes of tinea unguium in the USA (Elewski et al. 1995) as well as most other parts of the world.

Tinea favosa

Favus (meaning honeycomb) is now an exceedingly rare disease except in a few redoubts in central Africa and central Asia. It is usually caused by *T. schoenleinii*. Infections can be severe and chronic and involve pus formation in the hair follicles, a process producing cup-shaped crusts called scutula. Longstanding favus infections may result in alopecia with scarring.

Tinea imbricata

This chronic infection is caused by *T. concentricum*. Seven different clinical patterns of infection are distinguished: imbricate, featuring concentric rings of overlapping scales, lamellar, lichenified, plaque-like, annular, palmar/plantar, and ungual (Hay et al. 1984; Rippon 1988).

Dermatophyte pseudomycetoma

A distinct but uncommon dermatophyte infection is the invasion of subcutaneous tissue. In such infections, fungal elements form yellowish-white pseudogranules lacking any of the cementing material found in some true mycetomas. Granulomatous dermatitis is rare and is generally observed when a hair follicle ruptures and individual fungal hyphal elements escape into the dermis. This condition, also known as Majocchi's dermatophyte granuloma, results from instances of trauma to the infected skin. For example, a puncture wound may introduce the dermatophyte into deep tissue and facilitate invasion. Loose or compactly arranged hyphal aggregates of varying sizes embedded in eosinophil-rich Splendore–Hoeppli material may be erroneously referred to as granules or grains, by analogy with structures seen in mycetoma, and the lesions may indeed be referred to as mycetoma. However, the fungal aggregates may result from hair follicles with mycelial growth rupturing, permitting the mycelial filaments and fungal cells formed therein to escape into the surrounding dermis and continue to develop, eliciting a strong Splendore–Hoeppli reaction and granulomatous tissue response. Based on their loosely arranged mycelial aggregation surrounded by striking and abundant Splendore–Hoeppli reaction material, they should more appropriately be called pseudogranules and the lesion should be called a dermatophytic pseudomycetoma (Ajello et al. 1980; Chandler and Watts 1987). The most common cause of dermatophytic pseudomycetoma is *M. canis*. Other species that have been reported are *M. ferrugineum* and *M. audouinii* (Kwon-Chung and Bennett 1992).

IMMUNOLOGY

Dermatophytes colonize the keratinized tissue of the stratum corneum. The degree of inflammation produced in the lesions depends primarily on the species of the causal agent and, to some extent, on the immunological competence of the host. Infections by anthropophilic fungi, such as *T. rubrum*, often elicit less inflammatory response than is seen with infections caused by zoophilic and geophilic dermatophytes such as *T. verrucosum* or *T. mentagrophytes*.

Invasion by dermatophytes may be favored by environmental conditions. Warm, moist conditions are known to favor infection, as was seen in swampy areas of Vietnam featuring a high incidence of dermatophytosis in combat troops (Blank et al. 1969). Occlusion of sites exposed to dermatophyte inoculum appears to increase susceptibility. In experimental infections, this factor played a major role, apparently because it increased hydration of the underlying skin and retention of CO_2, helping dermatophyte growth (King et al. 1978).

Medical conditions such as collagen vascular disease, Cushing's disease, diabetes mellitus, hematological malignancy, atopy, and old age may play a significant role in predisposing patients to chronic dermatophytic infections, as may systemic corticosteroid therapy. Susceptibility to chronic dermatophytosis by *T. concentricum* may occur as an inherited trait (Hay 1992). An inherited autosomal recessive trait has been shown to predispose to infection by *T. concentricum* (Serjeantson and Lawrence 1977; Ravine et al. 1980). Similarly, susceptibility to chronic *T. rubrum* infection is likely to be mediated by inheritance of an autosomal dominant allele (Zaias et al. 1996).

Although a host develops a variety of antibodies as a response to a dermatophyte infection, including antibodies derived from immunoglobulins IgM, IgG, IgA, and IgE, it has been accepted that IgE plays a key role in the suppression of cell-mediated immunity (CMI), perhaps through modulating histamine activity. The variability seen among patients in humoral immunity responses to dermatophytosis has been attributed to a lack of standardized antigens and to differences in the sensitivity and specificity of the methods used (Matsumoto et al. 1996). It is known that CMI is the cornerstone of host defense in regard to dermatophytosis. The development of CMI, which is correlated with delayed-type hypersensitivity, is usually associated with clinical cure and with exclusion of the dermatophyte elements from the stratum corneum (Dahl 1993; Jones 1993). Delayed hypersensitivity responses to intradermal injections of trichophytin are commonly observed in the normal population (Wood and Cruickshank 1962; Palmer and Reed 1974; Grossman et al. 1975). These responses are probably caused by earlier exposures to dermatophytoses, or by crossreactivity with one or more related environmental organisms.

The immune response to dermatophytic infections has been investigated in human infections as well as in various experimental studies using calves, guinea pigs, rabbits, and rats. Experimental dermatophyte infections in animals appear to result in CMI to the antigens of the infecting dermatophyte (Cruickshank et al. 1960; Krebs et al. 1977; Green and Balish 1980). In guinea pigs with experimental infections caused by a member of the *T. mentagrophytes* complex, maximal erythema in the infected skin occurs at the time the infected animals developed CMI to trichophytin (Krebs et al. 1977). Similar findings have been noted in cattle experimentally infected with *T. verrucosum*. The delayed hypersensitivity reactions in the skin corresponded to clearance of infection by means of an increase in the desquamation rate of the stratum corneum (Lepper 1974; Lepper and Anger 1976; Wagner and Sohnle 1995). A live vaccine (LTF 130) against *T. verrucosum* ringworm in cattle was developed and successfully used to reduce infections in cattle herds in the former Soviet Union and some countries in eastern Europe (Segal 1989). The use of vaccine in humans, however, has not been effective.

TREATMENT

The increase in mycotic infections stimulated the pharmaceutical industry to develop new drugs to meet this challenge. The newer antifungal agents available to treat the dermatophytoses include orally active triazoles (fluconazole and itraconazole), the allylamines (naftifine and terbinafine), and the morpholines (amorolfine). These antifungals can be added to others currently in use, such as orally administered griseofulvin and itraconazole as well as topical antifungals such as haloprogin, the thiocarbonates (tolnaftate), hydroxypyridones (ciclopirox olamine), and numerous other imidazoles (Smith 1993; Gupta et al. 1994a).

Decisions regarding the best regimen for therapy must consider the extent, location, and clinical type of infection, the etiologic agent, the spectrum of activity and pharmacokinetics of the antifungal, any pharmacodynamic drug–drug interactions that may occur (Schafer-Korting 1993; Bickers 1994; Brodell and Elewski 1995), side effects (Hay 1993), cost (Einarson et al. 1994), and the overall risk/benefit analysis. The interested reader is referred to several reviews in which antifungal agents for the dermatophytoses are discussed along with their modes of action, dosages, therapeutic indications and contraindications, and drug–drug reactions (Elewski 1993; Stiller et al. 1993; Degreef and DeDoncker 1994; Gupta et al. 1994a, b; Brodell and Elewski 1995).

Oral antifungals are usually prescribed for tinea capitis, tinea unguium, chronic dry forms of tinea cruris, invasive infections, and infections resistant to topical therapy or with extensive involvement. These require extensive treatment before a clinical cure can be achieved. Generally, successful therapy necessitates compliance and good personal hygiene.

Tinea capitis

Oral griseofulvin has been the mainstay of therapy for tinea capitis since the 1950s. It is the most frequently prescribed therapy, usually requiring a 6-week course (Frieden and Howard 1994). No topical therapy has been shown to be as effective as oral griseofulvin, although topical applications of various preparations may be used as adjuncts to impede shedding of viable fungi from infected scalps (Del Palacio et al. 2000). Ectothrix infections caused by *M. canis* and other species of *Microsporum* usually respond best to griseofulvin (Jacobs 1990; Degreef and DeDoncker 1994); however, Jacobs (1990) considered ketoconazole as the first choice for treating endothrix infections caused by *T. tonsurans*.

Other studies indicate better results with oral ketoconazole (Gan et al. 1987; Tanz et al. 1988). Generally, oral ketoconazole is considered as an effective alternative when there is resistance, intolerance, or nonresponse to griseofulvin (Elewski 1994; Frieden and Howard 1994). Rare side effects, such as hepatotoxicity with long-term use of ketoconazole, limit its application to second-line treatment. Legendre and Escola-Macre (1990) and Elewski (1994) found itraconazole to be an effective alternative to either griseofulvin or ketoconazole. Gupta and colleagues (Gupta et al. 1997, 1998; Gupta and Adam 1998) investigated the efficacy of pulse therapy with itraconazole and terbinafine in children with *T. tonsurans* infections reporting 100 percent cure

rate when one to three pulses of itraconazole were used and 92 percent cure rate with terbinafine. Gupta et al. stated that, given the pharmacokinetics of both drugs, they found the pulse-dosing format to be a reasonable option. The pulse regimens allowed the physician to tailor therapy to the patient's response. Terbinafine, given orally, was found to be a safe and effective drug for treating tinea capitis (Haroon et al. 1992; Villars and Jones 1992).

Adjunct therapy may include selenium sulfide shampoos (Frieden and Howard 1994) or ketoconazole shampoo and topical econazole nitrate (Elewski 1994) to decrease inoculum shedding, as well as oral antibiotics to treat secondary infection and prednisone to diminish severe kerion (Frieden and Howard 1994). In addition to treatment with antifungals, general sanitation measures are necessary to prevent spread and recurrence of infection (Weitzman and Summerbell 1995). However, fomites and asymptomatic carriage contribute to spread and reinfection (Frieden and Howard 1994; Howard and Frieden 1995). Hebert et al. (1985) recommended treating not only the patient, but also all family members including adults, and sanitizing the home environment.

Tinea corporis

Tinea corporis, when caused by geophilic or zoophilic dermatophyte, usually resolves spontaneously within a few months. A variety of topical agents are usually applied to speed up healing of local and uncomplicated lesions (Smith 1993; Gupta et al. 1994a; Weitzman and Summerbell 1995). Topical imidazoles appeared to be highly effective with cure rates of up to 80 percent (Del Palacio et al. 2000). Amorolfine and allylamines are another alternative (Del Palacio-Hernanz et al. 1989; Del Palacio et al. 1991). Topical therapy is preferable because there is less potential for side effects. However, systemic therapy is also indicated for extensive lesions resulting from the anthropophilic dermatophyte species, for invasive lesions, and for chronic dry manifestations of tinea corporis caused by *T. rubrum*. For many years, oral griseofulvin and ketoconazole have been used as alternatives to treat recalcitrant or widespread lesions. However, griseofulvin-resistant mutants have rarely been reported (Artis et al. 1981). It has also been noted that one-third of patients do not respond to treatment with griseofulvin (Jacobs 1990). The therapeutic use of ketoconazole is limited by the rare side effects of this drug, such as liver toxicity and depressed adrenal activity and testosterone secretion (Kwon-Chung and Bennett 1992). Ketoconazole also has drug–drug interactions that may be problematical (Bickers 1994; Brodell and Elewski 1995). Itraconazole and terbinafine, taken orally, were reported to be generally safe and effective therapies against most of the common dermatophytes (Degreef and DeDoncker 1994; Gupta et al. 1994b; Weitzman and Summerbell 1995; Del Palacio-Hernanz et al. 1990; Del Palacio et al. 1993; Faergemann et al. 1997; Nozickova et al. 1998).

Tinea cruris

A variety of topical medications, applied as creams, lotions, or powders, may be used for uncomplicated tinea cruris (Smith 1993; Gupta et al. 1994a; Weitzman and Summerbell 1995). However, the dry recalcitrant type of infections caused by *T. rubrum* may require systemic therapy such as griseofulvin, itraconazole, fluconazole, or terbinafine (Gupta et al. 1994b). Relapses are more common with griseofulvin. Butenafine is effective in tinea cruris with 2 weeks of treatment, with a cure rate around 70 percent (Lesher et al. 1997). Fluconazole (150 mg once weekly) for 4–5 weeks has been effective in the management of tinea cruris and tinea corporis with a 74 percent clinical cure rate (Faergemann et al. 1997). Terbinafine was reported to be superior to griseofulvin in several studies (Degreef and DeDoncker 1994). Currently, itraconazole may be given as a dose of 400 mg/day given as two daily doses of 200 mg for 1 week as an effective treatment for tinea cruris infection (Del Palacio et al. 2000).

Tinea unguium

Tinea unguium, or dermatophyte infection of the nails, has generally been found to be difficult to cure. This has especially been noted with infections of the toenails, except in cases of superficial white onychomycosis. Tinea unguium was generally regarded as an incurable disease until the advent of systemic oral antifungal drugs. Previous treatment consisted of mechanical or chemical avulsion of the nail followed by topical therapy. Recurrence was, however, common. The use of older topical antifungal agents applied directly to the nail has given variable and disappointing results (Hay 1993; Hay et al. 1994) as a result of the inability of these agents to penetrate through the nail plate down to the nail bed where the fungus resides. Newer topically active antifungals, such as 28 percent tioconazole, amorolfine, and 8 percent ciclopirox, have produced higher remission rates than did older topical formulations, but overall cure rates have also been disappointing (Hay 1993). The use of the newer agents as an adjunct to oral antifungal therapy with griseofulvin improved recovery rates significantly (Hay 1993).

Griseofulvin was the first orally active, systemic antifungal agent applicable for the treatment of onychomycosis (fungal infection of the nail), but its use was limited to dermatophytes and required long-term therapy of 6–9 months for fingernails and 12–18 months for toenails (Roberts 1994). This was because it did not

diffuse into the nail bed but only reached the site of infection via uptake of newly produced nail keratin. In addition, without removal of the nail, overall cure rates of toenail infections were low, around 30–50 percent, and relapse was common (Roberts 1994).

Newer, orally active systemic medications have recently been shown to be effective when administered for short periods (up to 3 months) or when used intermittently. Both itraconazole and terbinafine reach the nail via incorporation into the matrix and remain unchanged in the nails at a therapeutic level for at least 6 months after termination of therapy in patients treated for 12 weeks (Hay 1993; Hay et al. 1994; Del Palacio et al. 1994, 1999). Either continuous therapy with itraconazole (200 mg/day) for 3 months or pulse therapy (200 mg twice a month) for 3–4 months may be used (Heikkila and Stubb 1997). The pharmacokinetic comparison of continuous and intermittent itraconazole pulse therapy showed that intermittent therapy resulted in relatively high itraconazole plasma concentrations but relatively low drug exposure. This resulted in a lower nail concentration of itraconazole in intermittent therapy than that obtained with continuous itraconazole therapy (Havu et al. 1999). However, this characteristic of intermittent therapy did not result in a reduced cure rate, as the concentration of itraconazole in the nail remained within the therapeutic range. The total itraconazole administered in pulse therapy was about half of what was given in a continuous therapy. This reduction in the amount of itraconazole administered reduced side effects and improved cost-effectiveness, in addition to providing increased convenience for the patient (Van Doorslaer et al. 1996; Nolting et al. 1998).

Nail removal plays a limited role in the therapy of onychomycosis (Hay 1993). It may be accomplished by surgery combined with the use of systemic antifungals before avulsion. Alternatively, it may be done chemically. The best known chemical procedure entails the use of 40 percent urea paste formulation under occlusion, sometimes with the incorporation of 1 percent bifonazole into the paste.

Although dermatophytes play a major role as causative agents of onychomycosis, nondermatophytic molds and yeasts account for a significant number of cases. Laboratory tests are needed to confirm the species involved and to rule out bacterial or nonfungal etiology; this will also ensure selection of the most effective treatment for each patient, and increase the probability of a complete cure (Elewski et al. 1995).

LABORATORY DIAGNOSIS

Direct microscopic examination

The direct microscopic examination of a properly collected specimen is one of the most rapid and effective methods of detecting a fungal infection. This highly effective screening technique will provide useful information regarding the etiologic agent, e.g. whether it is a mold or a yeast, and whether it causes ectothrix, endothrix, or favic hair invasion. In a few cases, direct specimen microscopy may suggest the genus of the causative agent.

The choice of method for the direct examination will depend upon the type of specimen screened and the laboratory's resources. The typical specimens submitted for the diagnosis of a dermatophyte infection are skin scrapings, hair stubs, and nail clippings or scrapings. The solutions usually chosen for the examination of these specimens are potassium or sodium hydroxide preparations, most commonly potassium hydroxide (10–20 percent KOH), often in combination with the fluorescent stain calcofluor white. In some laboratories and procedures, the periodic acid–Schiff (PAS) stain is used.

POTASSIUM HYDROXIDE

Potassium hydroxide is the most widely used preparation for the direct examination of clinical specimens for the presence of fungi. Basically, a drop of 10–20 percent KOH is placed on a slide, a small amount of specimen is added to the drop, a coverslip is placed over it and the preparation is gently heated (short of boiling). The KOH softens and clears the specimen for easier detection of hyphae by digesting any proteinaceous debris and disrupting the keratin's cellular sheets, thereby rendering the more biochemically resistant fungus more visible as highly refractile, hyaline, septate, branched, or unbranched hyphae and arthroconidia. In hairs, fungal elements may appear as arthroconidia on the outside (ectothrix invasion) of the hair shaft, or on the inside (endothrix), or they may appear as hyphae co-occurring with bubbles and tunnels (favic invasion). The reader is referred to several texts for descriptions and photographs of dermatophytes in invaded keratinized tissue (Fragner 1987; Rippon 1988; Weitzman et al. 1988; Kwon-Chung and Bennett 1992; Weitzman et al. 1995; Weitzman and Summerbell 1995; Kane et al. 1997).

Through the years, several modifications of the basic 10 percent KOH preparation have been made for more rapid detection. One modification is the incorporation of Parker superchrome blue-black ink in the KOH solution for selective staining of the fungus (Rippon 1988). Other modifications of the basic method include the addition of 36 percent dimethyl sulfoxide (DMSO) to 20 percent KOH to aid in the preparation and clearing of the specimen without heating (Rebell and Taplin 1974; Rippon 1988), and the addition of 5–10 percent glycerine to the KOH preparation (usually 10–25 percent for nails) to delay dehydration, crystallization of the KOH, and concomitant degradation of the fungal structures (Rebell and Taplin 1974; Weitzman and

Summerbell 1995). The slides are examined under the microscope with reduced light by lowering the condenser and adjusting the condenser's diaphragm.

Fungal hyphae must be differentiated from a variety of hypha-like artifacts such as cotton wool and synthetic fibers and from the so-called 'mosaic fungus.' This last artifact, which is more difficult to distinguish, consists of cholesterol crystals deposited around the periphery of the epidermal cells. It can be recognized by its regularity of outline, abrupt changes in width, presence of re-entrant angles in the flat crystalline structures, and lack of internal organelles (Rippon 1988). In experienced hands, the KOH preparation is one of the most useful and inexpensive diagnostic procedures in medical mycology.

CALCOFLUOR WHITE

Calcofluor white is a whitening agent used in the textile and paper industry. It binds to chitin and cellulose in fungus cell walls and fluoresces on excitation by long-wave ultraviolet rays or short-wave visible light. The use of this technique requires a fluorescent microscope with a proper ultraviolet source and a filter combination that may be too expensive for many laboratories. This method has, however, the advantage of allowing relatively easy fungal detection with reduced search time and a lower degree of technical experience (Elder and Roberts 1986). Calcofluor white can be combined with KOH for rapid clearance of the specimens. Fungal hyphae must be differentiated from textile fibers that may also fluoresce. Several publications are available describing calcofluor white application and technique (Hageage and Harrington 1984; Elder and Roberts 1986; Aslanzadeh and Roberts 1991; Harrington and Hageage 1991). Although background elements may also fluoresce, the fungal components are generally brighter and readily recognizable.

PERIODIC ACID–SCHIFF (PAS) STAIN

The PAS stain is based on the reaction of fungal cell wall polysaccharide with the PAS reagents, resulting in the fungus developing a red-violet fuchsin color in the tissue. This stain has also been applied successfully to histopathological analysis of nail plate clippings where onychomycosis was suspected (Suarez et al. 1991). One must be aware that a negative direct microscopic examination does not rule out the existence of a fungal infection.

Culture

ISOLATION MEDIA

Culture is a necessary adjunct to direct microscopic examination. It is only by culture that we can achieve definitive identification of the etiologic agent. In many instances, the choice of therapy may depend upon the specific identification of the invasive mold. This is especially important in nail and skin infections caused by nondermatophytic filamentous fungi, which are often resistant to the therapy used for dermatophyte infections (Summerbell et al. 1989).

A primary medium for the isolation of dermatophytes should be selective against bacteria and non-dermatophyte saprobic molds. Two such media that are commonly used are Sabouraud glucose agar (SGA) (a glucose peptone agar) with cycloheximide and chloramphenicol, and the dermatophyte test medium (DTM). Both media are available commercially and contain cycloheximide to inhibit saprobic contaminating molds. DTM incorporates gentamicin and chloramphenicol to inhibit bacteria and a phenol red indicator that changes color from yellow to red when the medium becomes alkaline as the result of growth of dermatophytes (Rebell and Taplin 1974). However, nonpathogenic fungi can also turn this medium red (Merz et al. 1970). Some systemically infecting fungi such as *Coccidioides immitis* (Salkin 1973) can resemble a dermatophyte on this medium, causing a serious biohazard situation. In addition, some dermatophytes, for example, *M. canis*, may give a false-negative reaction (Moriello and Deboer 1991). Therefore, DTM is a good screening medium for the isolation of dermatophytes but not a specific indicator of a dermatophyte. It also has the disadvantage of not allowing visualization of pigmentation on the reverse of the colony – a characteristic often used in identification. Clearly, for maximum yield of pathogenic fungi, it is important also to use a medium devoid of cycloheximide, especially for the culture of specimens from nails, soles and palms where nondermatophytic fungi sensitive to cycloheximide may be the causal agents (Summerbell et al. 1989; Weitzman and Kane 1991; Kane et al. 1997).

Nondermatophytic fungal elements may often resemble dermatophyte elements in direct microscopic examination, and hence culture on cycloheximide-free medium is necessary for their isolation and identification. The simple, commercially available, but effective, cycloheximide-free medium is SGA. If used without antibacterial agents, it allows bacterial growth from skin and nail specimens, and this may prevent the outgrowth of the fungi causing the infection. If used with chloramphenicol or with combined chloramphenicol and gentamicin, it can be very effective in the isolation of causal nondermatophytes; incidental contaminating fungi, of course, will also grow, and dermatophytes may do so as well. Other media containing antibacterial agents and lacking cycloheximide are inhibitory mold agar (BBL Microbiology Systems, Cockeysville, MD, USA) and Littman oxgall agar (Difco Laboratories Detroit, MI, USA) with added gentamicin and chloramphenicol (Summerbell et al. 1989; Weitzman and Kane 1991). Most of these media are available commercially. Specialized isolation media include: a Casamino acids/erythritol/albumin medium for the isolation of

dermatophytes from lesions heavily contaminated with bacteria or with cycloheximide-tolerant *Candida albicans* (Fischer and Kane 1974); and a bromcresol purple (BCP)/casein yeast extract agar designed for the isolation and recognition of *T. verrucosum* in specimens from rural areas (Kane and Smitka 1978). The addition of 0.1 percent yeast extract or thiamine to SGA may increase the isolation rate of dermatophytes, especially of *T. verrucosum* (Carmichael and Kraus 1959; Aly 1994).

Identification

Identification of a dermatophyte is based on its gross colonial morphology on SGA and on its microscopic morphology. These criteria, however, may not be sufficient, especially for *Trichophyton* spp. that resemble each other or are variable in appearance or atypical. In addition, some isolates do not sporulate readily and special sporulation media that may not be readily available are necessary to obtain sporulation. Thus, additional physiological and biochemical tests may be necessary in conjunction with gross and microscopic morphology for species identification.

COLONY CHARACTERISTICS

Gross colony characters observed on SGA include:

- color of the surface, i.e. of the aerial mycelium
- color of the reverse or obverse faces of the colony
- production of a diffusible pigment
- texture of the surface (glabrous or waxy, powdery, granular, suede-like, velvety, downy, or fluffy)
- topography (flat, cerebriform, crateriform)
- growth rate.

These features are best noted when cultures are grown on Petri dishes rather than in tubes.

MICROSCOPIC MORPHOLOGY

Microscopic morphology may be studied in teased mounts, slide cultures (Riddell 1950; Larone 1995), or pressure-sensitive tape preparations (Rebell and Taplin 1974; St Germain and Summerbell 1996); they are examined for micro- and macroconidia and the other structures described in Tables 4 and 5. These preparations may be mounted in lactophenol cotton blue (Poirrer's blue) or lactophenol aniline blue (St Germain and Summerbell 1996). Specialized media that may be necessary to stimulate sporulation include corn meal, potato flake, potato glucose, Sabouraud's glucose + 3–5 percent NaCl (Kane and Fischer 1975), lactrimel (Kaminski 1985) and autoclaved polished rice grains (McGinnis 1980). The formulas for these media are found in several textbooks (McGinnis 1980; Rippon 1988; Kwon-Chung and Bennett 1992; de Hoog et al. 2000).

PHYSIOLOGICAL TESTS

In vitro hair perforation test

This test (Ajello and Georg 1957; Padhye et al. 1980; Clayton and Midgley 1989) originally devised to distinguish atypical isolates of *T. mentagrophytes* and *T. rubrum* (Ajello and Georg 1957), may also be used to distinguish *M. equinum* from *M. canis* (Padhye et al. 1980). *T. mentagrophytes* and *M. canis* perforate hair whereas *T. rubrum* and *M. equinum* do not. This test is also helpful in identifying other dermatophyte species (Padhye et al. 1980).

Production of urease or urea hydrolysis

The ability to hydrolyze urea (Philpot 1967; Clayton and Midgley 1989), in either an agar or a broth medium, aids in the distinction of *T. rubrum* (urease-negative) and *T. mentagrophytes* (urea-positive). The dermatophyte *Trichophyton raubitschekii*, considered by some mycologists to be a variant of *T. rubrum* (Kwon-Chung and Bennett 1992; Summerbell et al. 1999; Gräser et al. 2000a, c) or as a distinct species by others, is urease-positive (Kane et al. 1981). *T. megninii* [considered by some (Gräser et al. 1999a, 2000c) to be synonymous with *T. rubrum*] is urease positive in a urea-indole broth (Sequeira et al. 1991), but may be negative on Christensen's urea medium, whereas *T. rubrum*, apart from the relatively uncommon afro-asiatic isolates sometimes separated as *T. raubitschekii*, is urease-negative in both media (Rosenthal and Sokolsky 1965; Sequeira et al. 1991). Both Christensen's urea agar and broth media may be used. A broth medium is, however, preferred over the agar medium because it is more sensitive (Kane and Fischer 1971). The test is considered negative if there is no color change from straw to reddish purple within 7 days at 23–30°C. Cultures to be tested must be pure, because the presence of bacteria can produce a false-positive reaction. When in doubt about the purity of a culture, incubate the test culture on a blood agar medium to detect the presence of bacteria, before carrying out the urease test.

Nutritional requirements

A series of vitamin and amino acid test agars that is available commercially as trichophyton agars 1–7 (Difco, Remel, Lenexa, KA, USA) is used to distinguish some *Trichophyton* spp. by demonstrating their requirements for special growth factors (Georg and Camp 1957; Clayton and Midgley 1989). Trichophyton agar no. 1 is a vitamin-free casein basal medium to which various growth factors have been added, namely, inositol for Trichophyton agar no. 2, inositol and thiamine for no. 3, thiamine for no. 4, and nicotinic acid for no. 5. Ammonium nitrate basal medium makes up Trichophyton no. 6, and the same medium with added histidine makes up

medium no. 7. The special nutritional requirements are indicated in descriptions of the *Trichophyton* spp. in Table 5. Care must be taken to avoid vitamin and amino acid carryover from the transferring agar and to avoid use of large inocula.

Additional useful tests for identification may include examination of the type of growth and change of indicator color occurring on bromcresol milk solids glucose agar (Padhye et al. 1973; Kane et al. 1987; Summerbell et al. 1988; Weitzman et al. 1995), a test for growth on autoclaved polished rice grains, and tests for temperature tolerance and high-temperature enhancement of growth (Clayton and Midgley 1989; Weitzman et al. 1995). Details regarding the preparation of these media, performance of these tests, and their results are discussed by Kane et al. 1997, Clayton and Midgley 1989, Ellis et al. 1992, St Germain and Summerbell 1996, and Weitzman et al. 1995.

Histopathology

Dermatophyte infections are generally restricted to the horny epidermal layers of the skin. A toxic reaction in the epidermis is often the first response to the presence of the fungus in the stratum corneum. It presents as an eczemiform pattern or as a nonspecific, subacute, chronic dermatitis. If the biopsy tissue is from a dry scaly area, hyperkeratosis and parakeratosis are seen. Special fungal stains demonstrate mycelium in the horny layer of the skin. In tinea capitis, there is no specific histological picture for dermatophytic infections. Fungal hyphal elements are seen sparsely in the stratum corneum penetrating through the squames. Hyphae extend down into the hair shaft and penetrate hair lying parallel to them. Hyphal tips growing down within the shaft reach to the edge of living keratinizing cells and form 'Adamson's fringe.' The overall pattern in ringworm of the scalp is that of a subacute or chronic dermatitis. The newly keratinized material of the growing hair extending through the aperture of the follicle carries, either within it (endothrix) or surrounding the cuticular surface (ectothrix), hyphal elements of the invading fungus which break up into arthroconidia. In tinea favosa, mycelium is present in the horny layer of the scalp, within and around the hairs, and in the scutulum. The scutula consist of mycelial masses, scales, sebum, and other debris, cementing together to form a cup-shaped crust (Rippon 1988; Weitzman and Summerbell 1995). Development of a hypersensitive kerion reaction on the scalp is accompanied by infiltration of lymphocytes, plasma cells, eosinophils, and neutrophils into the dermis (Kwon-Chung and Bennett 1992).

In the most common, distal-lateral subungual type of tinea unguium, fungi are readily seen in infected nail sections stained with PAS. Filamentous hyphae and arthroconidia are generally aligned horizontally between lamellae of the nail and restricted to the lowermost portion of the nail. There is little or no inflammation in the underlying tissue. The etiologic agent is usually *T. rubrum*, though *E. floccosum* can also be involved. By contrast, in superficial white onychomycosis, infection is restricted to the surface of the nail and is characterized by irregular hyphae that are flattened with frond-like branches that spread out between keratin lamellae. The etiologic agent is generally *T. interdigitale*, but *Fusarium oxysporum*, *Acremonium* spp., and *Scopulariopsis* spp. are among numerous other organisms that may also be involved.

A rare but distinctive clinical manifestation of dermatophytosis is invasion of the subcutaneous tissue with formation of yellowish-white pseudogranules. These structures measure 80–500 μm in diameter and consist of septate hyphae, frequently vesiculate, surrounded by a thick, radiating coat of Splendore–Hoeppli eosinophilic material. Most of the causal agents are *Microsporum* spp. or *T. rubrum* and patients are often north Africans, Australian aboriginals, and African-Americans (Chandler et al. 1980; Kwon-Chung and Bennett 1992).

PREVENTION AND CONTROL

The prevention and control of dermatophytic infection depend on the area of the body involved, the causal agent, and the source of infection. In connection with scalp ringworm caused by *M. audouinii*, all contacts with infected individuals should be carefully examined using Wood's light for fluorescent hair. In *M. canis* infections, likely pet animal sources should similarly be examined along with other persons who may have been in contact with them. In chronic care and scholastic residential institutions where *M. canis* may spread widely from a single index patient who has contacted an infected animal, all inmates (e.g. patients, students) and staff should be examined. In case of nonfluorescent tinea capitis caused by *T. tonsurans* and *T. violaceum*, scalp examination should be done more carefully for spotty alopecia and scaly lesions. Hair from suspicious areas should be cultured regularly. The hairbrush method (Mackenzie 1963) may be helpful in collecting scalp hair from children. In populations and geographical areas with an ongoing tinea capitis problem, routine scalp examinations of young school children should be done on a regular basis to avoid large-scale outbreaks. Good hygiene and avoidance of sharing headgear, combs, and hairbrushes should be stressed to students. Barbershop instruments should be disinfected after use. All children or adults infected with ringworm of the scalp should be treated promptly to prevent further transmission of their infections.

Nosocomial spread of dermatophytosis, although rare, has been reported in recent years (Mossovitch et al. 1986; Kane et al. 1988; Shah et al. 1988; Arnow et al.

1991; Snider et al. 1993). In one such outbreak, caused by *T. tonsurans*, the infection was transmitted from an infected child to hospital personnel (Arnow et al. 1991). Two other outbreaks resulted from transmission of *M. canis* to neonates by nursing personnel (Mossovitch et al. 1986; Snider et al. 1993). Such nosocomial outbreaks should be investigated promptly to avoid further dissemination. Involved personnel and direct contacts should be screened using Wood's light, and scrapings from suspected areas of skin and scalp should be cultured. Until the source of infection in a nursery is identified and treated, protective clothing should be worn by healthcare workers to avoid direct contact.

Tinea corporis and tinea cruris caused by anthropophilic species can be transmitted by contaminated clothing, bedding, towels, etc., and these should be washed and disinfected before being used by other people. Individuals with tinea infection of the glabrous skin should also avoid contact sports such as wrestling. A number of recent dermatophytic outbreaks among high school and college wrestlers have been reported in recent years (Stiller et al. 1992; Beller and Gessner 1994).

When zoophilic species such as *M. canis*, *T. mentagrophytes*, and *T. verrucosum* are detected as etiologic agents, infected animal reservoir sources should be sought out and treated. Infections caused by *T. verrucosum* are difficult to detect with the use of Wood's light because infected hairs do not fluoresce, and the shed, infected scales have been shown to survive for years on fomites. Good hygiene and sanitation, and use of fungicidal sprays and washes, are effective methods for prevention of such infections (Weitzman and Summerbell 1995).

The spread of tinea pedis infections may be controlled by good foot hygiene, use of antifungal powders, avoiding excessive moisture, and occlusion of feet by wearing sandals or ventilated footwear, and avoiding walking barefooted in swimming pool areas, community baths, and shower areas. Prompt treatment of individuals with tinea pedis should be undertaken to avoid spread of infection.

Dermatomycotic molds

COLIN K. CAMPBELL AND ELIZABETH M. JOHNSON

Skin and nail infections	1	Descriptions of mold fungi causing onychomycosis and dermatomycosis	5
Infections by *Scytalidium* spp.	3	Treatment of onychomycosis and dermatomycosis caused by molds	9
Infections by *Aphanoascus fulvescens* (*Anixiopsis stercoraria*)	4	References	10
Infections by *Onychocola canadensis*	4		
Otitis externa	4		

Although the dermatophytes show considerable adaptation to their life as epidermal parasites, it is clear that most other fungi are unable to invade keratinized tissue. In those cases where nondermatophyte molds are recognized as superficial pathogens, the affected site is remote from living tissue, as in the extremities of the nails, or there is structural and presumably biochemical abnormality of the keratin as a result of trauma or preexisting disease. Very few molds have been able to invade the epidermis of unaltered skin in the way dermatophytes can, and only the tropical ascomycete, *Piedraia hortai*, invades hair. This chapter describes the characteristics of mold infections of skin and nail, and of otitis externa, together with the distinguishing features of species commonly involved.

SKIN AND NAIL INFECTIONS

Clinical features

The main clinical features, etiological aspects, and therapy of nail infections have been reviewed (Midgley et al. 1994; Denning et al. 1995). Estimates of the importance of molds, compared with dermatophyte fungi in skin and nail infections, vary considerably. Summerbell et al. (1989) reported that less than 10 percent of isolations from infected nails were nondermatophytes. Of these, half were yeasts (mostly *Candida* spp.) and half were various mold species. Certain classes of patient show a raised incidence of nondermatophyte molds in nails. In particular, elderly or immunocompromised individuals and patients with keratin abnormalities may be affected. Such infections are more often reported from toenails than fingernails. English and Atkinson (1972), using the efficient sampling method of pulverized nails, estimated that 18 percent of elderly chiropody patients seen and 68 percent of those with positive direct microscopy and culture, were infected by molds.

Two main types of nail infection have been recognized: the common distal and lateral subungual onychomycosis and the less common superficial white onychomycosis. Both are typically caused by dermatophyte fungi such as *Trichophyton rubrum* and *Trichophyton mentagrophytes* var. *interdigitale* in addition to a number of mold species. In the case of the molds, infection is often confined to a single nail. In the distal subungual form, the fungus invades underneath the free end of the nail plate, eliciting a hyperkeratotic response in the nailbed epithelium. This results in a build-up of amorphous keratinized tissue, greatly thickening the nail and, in time, lifting the nail plate to an angle of 30° or more from its original position.

Although the hard nail plate may be invaded, the softer amorphous material is the major site of invasion by the fungal mycelium. A variety of yeasts and bacteria may also grow in this material and it is difficult to attribute sole pathogenic role to the presence of the mold. Many affected nails become discolored, possibly resulting from the mixture of organisms present and from the opacity of the amorphous keratin itself.

In superficial white onychomycosis, the fungus infects the top surface of the hard nail plate, and slowly erodes the keratin to give a white powdery area. The disease seldom progresses beyond the superficial layers of the nail plate and there is no response by the underlying nail bed epithelium.

Diagnosis

As most nondermatophyte species invading keratinized tissue are also common saprophytes (a few are plant parasites), some authors have stressed the importance of assessing the significance of isolation from diseased sites. This is done by the demonstration of hyphae in tissue and by growth of a mold in pure culture from most tissue samples. Growth of one or only a few colonies from perhaps 10 or 20 samples cannot be interpreted, especially in the absence of direct observation of hyphae in the tissue, because they may have grown from dormant spores contaminating the skin or nail. Unfortunately not all reports of mold infection have made this distinction. Zaias et al. (1969) reported isolation of mold species from 183 abnormal toenails and demonstrated that KOH-negative nails could yield a profusion of saprophytic molds in culture.

If there is ready access to a fluorescence microscope, then use of the optical brightener calcofluor white can enhance the detection of fungal elements in skin, nail, and hair specimens. For skin and hair specimens, calcofluor white can be used in equal proportion to KOH and placed over the specimen on a microscope slide, covered with a coverslip and left to digest for at least 20 minutes. During this time the slides should be protected from light. It is important that nail samples are presoftened before the addition of calcofluor white or it is unable to penetrate the tissue.

Microscopic examination will reveal the presence of any fungal hyphae. It is a feature of dermatophyte infections that the production of the asexual conidia is suppressed in the infectious state, with direct microscopy of the tissue revealing only vegetative hyphae, some of which may show fragmentation into arthroconidia. Thus, chains of rectangular spores are typical of dermatophyte infection but are not usually seen in mold-infected nails; this is therefore an important feature to note as it may help in the assessment of significance of a subsequent mold isolate. Some molds, such as *Scopulariopsis brevicaulis* and *Scytalidium dimidiatum*, may be distinguished from dermatophytes on direct examination. Mold hyphae may produce fronding which is not usually seen with dermatophyte hyphae and occasionally, when there is an air pocket in the nail, sporing structures may be visible within the nail preparation (Figure 1). Molds usually infect nails damaged either due to trauma, disease, or underlying dermatophyte infection and sometimes form fungal balls within the nail plate.

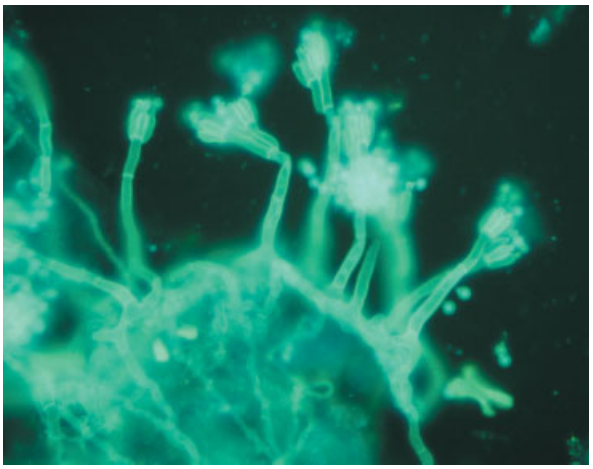

Figure 1 *Calcofluor staining of a nail specimen infected with a* Penicillium *sp. demonstrating the production of sporing structures produced in an air pocket within the nail*

The common use of cycloheximide in agar culture media for selection of dermatophyte fungi may mask the presence of infectious molds in skin and nail because this drug is inhibitory to most saprophytic molds. Many laboratories now use a cycloheximide-free medium for isolation from nails in addition to the routine medium. It should be remembered, however, that mold infections of the skin do occur (see sections on Infections by *Scytalidium* spp., Infections by *Aphanoascus fulvescens* (*Anixiopsis stercoraria*) , and Infections by *Onychocola canadensis*), and these will also require a less selective medium.

Isolation of a mold is not considered significant if direct microscopy was negative; a repeated attempt at isolation of a dermatophyte should also be considered if chains of arthroconidia were observed on direct microscopy as these are more indicative of a dermatophyte infection. If a mold is isolated from a specimen from which a dermatophyte is recovered, the mold is likely to be an incidental contaminant. In a study of onychomycosis, Ellis et al. (1997) reported the presence of a mold or yeast in addition to a dermatophyte in 64 percent of 118 patients. Significantly, only three of these patients (2.5 percent) yielded the same yeast or mold from two or more consecutive specimens.

Etiology

The relative incidence of the mold species reported in nails varies from one study to another, but it is clear that *Scopulariopsis brevicaulis* (see section on *Scopulariopsis brevicaulis* Bainier below) is the mold most readily acknowledged as capable of causing nail dystrophy. It is one of the few molds that appears to be able to infect otherwise healthy nails and can sometimes be identified on microscopy of an infected nail because of its propensity to produce conidia in vivo. Microscopy reveals broad, septate hyphae, which are easily distinguished from those

of dermatophytes. A few reports exist of onychomycoses caused by other *Scopulariopsis* spp., including *Scopulariopsis acremonium*, *Scopulariopsis asperula*, *Scopulariopsis fusca*, and *Scopulariopsis koningii* (Krempl-Lamprecht 1970; Schönborn and Schmoranzer 1970), and *Scopulariopsis flava* (Piontelli and Toro 1988).

Next in order of frequency to *S. brevicaulis* are species of *Aspergillus*, *Acremonium*, and *Fusarium*. The species causing deep aspergillosis have all been described from nails, although the *Aspergillus versicolor* group (including *Aspergillus sydowii*), the *Aspergillus glaucus* group, and *Aspergillus candidus* (see sections on *Aspergillus versicolor* (Vuill.) Tiraboschi, *Aspergillus glaucus* group, and *Aspergillus candidus*) are probably more frequent (Walshe and English 1966; Zaias 1972). As with onychomycosis caused by *Scopulariopsis* spp., a small number of reports involve well-documented cases of infection by related but little-known species. These include *Aspergillus hollandicus*, a member of the *A. glaucus* group (Grigoriu and Grigoriu 1975), *Aspergillus restrictus*, *Aspergillus unguis* (Schönborn and Schmoranzer 1970), and *Aspergillus sclerotiorum* (Feuilharde de Chauvin and de Bièvre 1985; Garcia-Martos et al. 2001). Reports of onychomycosis caused by *Fusarium* and *Acremonium* (*Cephalosporium*) spp. usually have not carried the identification beyond genus level (Walshe and English 1966; Zaias 1972; McAleer 1981; Vélez and Díaz 1985), although experience suggests that *Fusarium solani*, *Fusarium oxysporum*, and *Acremonium strictum* are the most common (see sections on *Fusarium solani* (Mart.) Sacc., *Fusarium oxysporum* Schlecht, and *Acremonium strictum* W. Gams, respectively). There have been reports in neutropenic patients of disseminated infections with *Fusarium* spp. arising from cutaneous lesions associated with infected nails (Merz et al. 1988; Girmenia et al. 1992). *Paecilomyces variotii* and *Paecilomyces lilacinus* are occasionally implicated in nail infection (see Arenas et al. 1998 for a review of onychomycosis due to *P. variotii*). Onychomycosis due to *Alternaria* spp., in particular *Alternaria alternata*, is rare, but there are several reports suggesting their involvement (Wadhwani and Srivastava 1985; Singh et al. 1990; Glowacka et al. 1998; Romano et al. 2001)

In patients of tropical origin, onychomycoses can result from *Scytalidium hyalinum* and *Scytalidium dimidiatum*. These, together with the mold recently described from nails as a new genus and species, *Onychocola canadensis*, are discussed in detail below. Other molds are occasionally reported, some of which may have been implicated without a careful appraisal of their true significance. Those with good evidence of infection are summarized in Table 1.

INFECTIONS BY *SCYTALIDIUM* SPP.

Gentles and Evans (1970) were the first to report human infection by *S. dimidiatum* (under its earlier name, *Hendersonula toruloidea*; see section on *Scytalidium dimidiatum* (Penz.) Sutton and Dyko (pycnidial synanamorph *Nattrassia mangiferae* (Sydow and Sydow) Sutton and Dyko)). First described in 1933 as a cause of die-back and wilt disease in stone-fruit trees in Egypt, it had become well recognized as an important pathogen of a wide range of tropical crop plants. Over a period of 7 years, Gentles and Evans collected eight cases of a condition clinically indistinguishable from tinea pedis, in which this species was the only isolate recovered, sometimes repeatedly. In four cases, the skin of the palms or fingernails was also involved. Most patients were middle-aged male immigrants to the UK from tropical countries. Subsequent reports from other UK laboratories (Campbell et al. 1973; Moore 1978) followed and established this fungus as a frequent cause of infection of both hands and feet in people who originated from tropical countries. More recently, reports have appeared of its occurrence as a human pathogen in Canada

(Summerbell et al. 1989), Nigeria (Gugnani and Oyeka 1989), Sweden (Rollman and Johansson 1987), Spain (Revilla et al. 1992), Thailand (Kotrajaras et al. 1988), and the USA (Greer and Gutierrez 1987; Frankel and Rippon 1989; Elewski and Greer 1991).

Unusually for nondermatophyte pathogens, *S. dimidiatum* and *S. hyalinum* (see section on *Scytalidium hyalinum* Campbell and Mulder below) are able to invade the skin as well as nails, mimicking tinea manuum and tinea pedis caused by the dermatophyte *T. rubrum* (Hay and Moore 1984). The microscopic appearance of the infectious hyphae in skin shows, however, great variation in width along any one length and some hyphae are twisted and contorted, unlike the appearance of typical dermatophyte hyphae (Campbell et al. 1973).

During an investigation into the occurrence of *S. dimidiatum* infections, several cases of essentially the same disease entity were encountered in which the isolated fungus was a white arthroconidiate mold. Campbell and Mulder (1977) described eight such cases and named the organism *Scytalidium hyalinum*. All occurred in immigrants from the Caribbean area or west Africa. Moore (1986) later described the same species in 11 other British immigrants, also originating from these areas. Pointing to the many parallels in the clinical presentation, conidiogenesis, and antigenic composition of these two species, Moore suggested that *S. hyalinum* could merely be a nonpigmented variant of *S. dimidiatum*. This is now supported by DNA comparisons (Roeijmans et al. 1997).

A small survey carried out on hospital attendees in Tobago indicated that infections by this fungus may be common in some tropical areas (Allison et al. 1984). Of 45 patient samples, seven showed microscopic and/or cultural evidence of *S. hyalinum*, and three others yielded *S. dimidiatum*. With the figures added for positive microscopy but failed culture, almost half the total population studied would appear to have had some form of *Scytalidium* spp. infection. None of these people was aware of the infection. Possibly patients referred to clinics in the UK have been motivated by severity of the lesions. Reports of *S. hyalinum* infections have also come from Canada (Summerbell et al. 1989), the USA (Elewski and Greer 1991), Australia (Maslen and Hogg 1992), and Nigeria (Gugnani and Oyeka 1989).

INFECTIONS BY *APHANOASCUS FULVESCENS* (*ANIXIOPSIS STERCORARIA*)

Although rare (it is the subject of only a handful of case reports), this keratinophilic soil fungus (see section on *Aphanoascus fulvescens* (Cooke) Apinis below) stands out as unusual among nondermatophyte molds in that it apparently invades skin rather than nail; it is, however, unwise to rule out the possibility of nail infection. Ringworm-like lesions with epidermal scaling have been described on thighs (Rippon et al. 1970), arms (Albala et al. 1982), neck (Marín and Campos 1984), and scalp (Guého et al. 1985), and similar infections have occurred in animals (Rippon et al. 1970; Vanbreuseghem and de Vroey 1980). In most of these cases, the anamorphic state – a *Chrysosporium* sp. close to *Chrysosporium keratinophilum* – was isolated, and the *Aphanoascus* state developed on prolonged incubation. Other *Chrysosporium* spp. have also been associated with skin lesions (de Hoog et al. 2000).

INFECTIONS BY *ONYCHOCOLA CANADENSIS*

Onychocola canadensis (see section on *Onychocola canadensis* Sigler below) is a slow-growing, arthroconidiate hyphomycete which was first reported in Canada from nail and skin infections (Sigler and Congly 1990), although evidence of skin infection was not supported by positive microscopy. Since then the organism has been reported from a number of other countries, including France (Contet-Audonneau et al. 1997), Spain (Llovo et al. 2002), New Zealand (Sigler et al. 1994), and the UK (Campbell et al. 1997) where it is referred to the Mycology Reference Laboratory for identification several times a year. There has also been a further more extensive report of cases in Canada and a review of the literature (Gupta et al. 1998).

Microscopy of the subungual keratin from infected nails shows a picture distinct from that seen with dermatophytes. There are septate, hyaline, branching hyphae of varying widths reminiscent of those seen from infections with *S. dimidiatum* and *S. hyalinum*. The round-to-barrel-shaped arthroconidia are more rounded than the cylindrical arthroconidia seen in dermatophyte infections. There are also unusual thick-walled, light-brown hyphae which may be a feature of chronic infections as similar hyphae are only produced on prolonged culture in vitro.

The environmental source of *O. canadensis* has not been established, but it is likely to be a soil saprophyte in common with other nondermatophyte agents of onychomycosis. In vitro studies have shown that it is unable to break down the keratin of hair, but weak cellulolytic activity has been demonstrated. As elderly individuals are most often affected, it appears that altered keratin may be necessary for infection. A description of its teleomorph, *Arachnomyces nodosetosus* sp. nov., was published by Sigler et al. in 1994.

OTITIS EXTERNA

Fungal infections of the ear are common conditions in which there is infection, usually of the external auditory canal, with fungi that are either spread by airborne conidia or derived from direct invasion of the epithelium

through the external canal (Kaur et al. 2000; Ozcan et al. 2003). Examples of the former include *Aspergillus* spp., and of the latter, dermatophytes. Sometimes cutaneous pathogens cause this condition, but their presence is likely to have followed airborne contamination by spores, e.g. *S. brevicaulis* (Besbes 2002). Rarely, otitis externa may follow dissemination of a systemic fungal infection such as coccidioidomycosis (Harvey et al. 1978). As such, the pathogenetic role of each organism has to be carefully weighed against the pathological response, as in some cases it is likely that the isolation of a fungus is merely a reflection of temporary carriage of the organism in the external canal. Growth of the fungus by itself can cause loss of hearing due simply to obstruction of the lumen. *Aspergillus niger*, for instance, is a common cause of this form of hearing loss (Loh et al. 1998). The main organisms isolated are *Aspergillus* and *Candida* spp., a whole range of different environmental fungi including *Scedosporium apiospermum* have been implicated (Milne et al. 1986). Rarely, infection may result in an acute and severe destructive process with subsequent invasion of adjacent tissue, malignant otitis externa (Bellini et al. 2003). This is a rare event and mainly associated with profound immunosuppression; the commonest cause is bacterial infection with *Pseudomonas*, but fungi such as *Aspergillus* spp. are occasional causes (Bellini et al. 2003). Other even rarer causes have included *Malassezia pachydermatis* (Chai et al. 2000) and *Absidia corymbifera* (Paterson et al. 2000).

Factors predisposing to infection of the external auditory canal range from existing disease of the external canal such as seborrhoeic dermatitis, eczema, or psoriasis, to trauma and climatic conditions. The latter seem to be particularly important as overgrowth of organisms such as *A. niger* is more common in tropical and humid conditions (Schuster et al. 2002). It is also apparent that in many cases there is mixed growth of different organisms from the canal.

The pathogenesis of fungal otitis externa is not always clear. As stated previously, growth of fungi may simply reflect colonization with growth exacerbated by climatic conditions or other factors such as the administration of antibiotics. However, the excessive growth of fungi may physically obstruct the narrow lumen. Otherwise, invasion is almost always confined to the epithelium except in malignant otitis externa (Vennewald et al. 2003). In addition, in some cases of *A. niger* infection local deposition of oxalate crystals may contribute to underlying tissue damage (Landry and Parkins 1993).

The main clinical features of fungal otitis externa are irritation and discharge from the external auditory canal (Kurnatowski and Filipiak 2001). There may also be hearing impairment due to the production of wax, scaling, or fungal growth. On inspection, the ear canal is usually reddened and may have an inflammatory exudate. If *A. niger* is present, the fungal growth may appear as a dark mat and black fruiting heads are seen together with accompanying oozing and scaling. The malignant form of otitis externa shows ulceration and necrosis with bleeding. There may be pain, often indicating deeper extension into the mastoid ear cells.

Fungi may also be found deeper in the middle ear in association with chronic otitis media. Once again their pathogenic role is not clear and many are contaminants. The organisms isolated from this site are similar to those found in otitis externa (Vennewald et al. 2003).

These infections are managed through a variety of different techniques such as local toilet including debridement and intensive cleansing (Kurnatowski and Filipiak 2001). Topical antifungals such as ciclopirox olamine (del Palacio et al. 2002), 1 percent bifonazole (Falser 1984), clotrimazole, nystatin, or the application of gauze packs soaked in a 1 percent azole solution have also been used. These are repeatedly changed. Oral or intravenous therapy is indicated for necrotizing infections.

The external ear itself may also be affected by facial infection, the commonest of which is *T. rubrum*. However, rarer infections such as chromoblastomycosis and lobomycosis may also affect the external ear. *Rhinosporidium* may also involve this area.

DESCRIPTIONS OF MOLD FUNGI CAUSING ONYCHOMYCOSIS AND DERMATOMYCOSIS

Acremonium strictum W. Gams

Colonies are moderately fast growing, attaining a diameter of 50 mm in 1 week at 30°C. The surface is flat to slightly folded and may be covered in a loose network of aerial hyphae, or may be wet and almost glabrous. The predominant color of the aerial growth is pale salmon pink, although the more floccose strains may be white. Microscopically there is an abundance of small (3.5–5×1–2 μm) conidia, cylindrical to ovoid in shape, which are produced sequentially from the phialidic tips of long, slender, lateral hyphae (Figure 2). These arise from bundles of aerial hyphae. The conidiophores can be viewed in situ on the colony using a binocular dissecting microscope, when each phialide can be seen to carry a droplet-like mass of conidia, held together by surface tension.

Alternaria alternata (Fr.) Keissl

The genus *Alternaria* is characterized by producing branching chains of multicellular conidia with dark pigmented walls and septa arranged longitudinally, transversely, and obliquely. The group are mostly pathogens of plant leaves, but *A. alternata* seems to be mainly saprophytic and is a common laboratory contaminant.

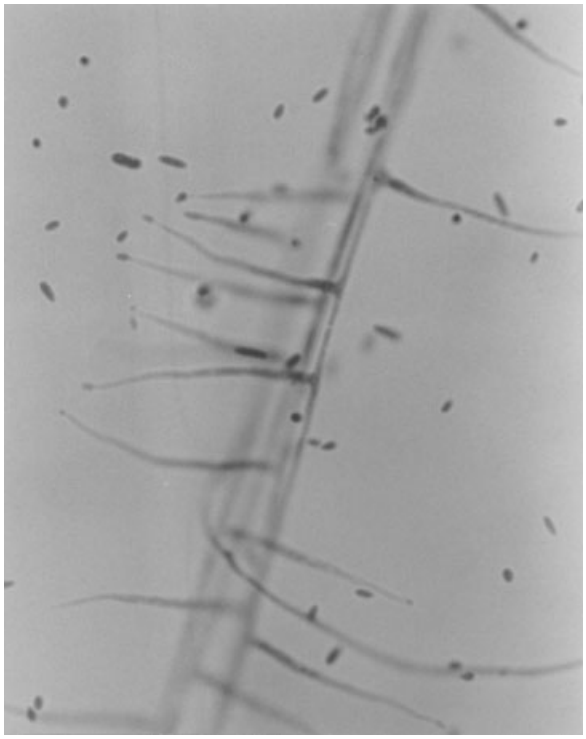

Figure 2 Acremonium strictum*: slide culture preparation showing delicate lateral phialides with terminal conidia. In this mount all but the last-formed conidia have dispersed into the mounting fluid. In life they are aggregated in round heads on the phialide apices.*

On normal media it grows as a cottony white colony which slowly develops black pigment in the center. On less rich media the colonies are black to dark brown, suede-like or powdery, and abundent conidia are produced. Conidia are typically clavate, about 25–50 μm long, with a short apical beak which produces the successive conidium in the chain.

Aphanoascus fulvescens (Cooke) Apinis

Colonies are of medium growth rate, flat and felt-like, white to cream in color. On prolonged incubation, a ring of pale purple–brown ascocarps develops near the center. On microscopy there are many club-shaped aleurioconidia, of similar shape to the microconidia of dermatophytes but much larger (mostly 10–15×4–6 μm) and frequently slightly curved. This is the conidial state (*Chrysosporium* spp.). The *Aphanoascus* teleomorph is a smooth-walled ascocarp, up to 500 μm diameter, with pale-brown, rough-walled, ovoid ascospores in round asci.

Aspergillus versicolor (Vuill.) Tiraboschi

This is an *Aspergillus* sp. of moderate growth rate, reaching 10–20 mm diameter in 1 week. *A. versicolor* is so called because it can appear in a variety of colonial colors, ranging from shades of green, light brown, yellow, and grayish pink. The conidial color is, however, dull gray–green and this dominates in cultures that spore well. Microscopically, the distinguishing features are the small head, consisting of an ovoid vesicle that bears supporting cells (metulae) below the layer of phialides (i.e. biseriate heads). There may also be reduced heads resembling those of *Penicillium* spp. *A. sydowii*, often reported from nails, is microscopically identical but has a blue–green colony color. Some mycologists place it as a variant of *A. versicolor* (Figure 3).

Aspergillus glaucus group

The name *A. glaucus* is no longer used as a single species but represents an assemblage of closely related aspergilli separable mostly on the basis of their sexual ascosporic states. The colony is generally slow growing on normal media, but this can often be accelerated on special media with low water activity. On glucose peptone agar, the surface is granular and colored mid-green (conidia), with areas of bright-yellow ascocarps. Microscopically, the heads are small relative to the wide stalks, and are composed of small phialides mounted directly upon the subspherical vesicle. In many strains aberrant heads, consisting of secondary conidiophores radiating out from the vesicle, may be seen.

Aspergillus candidus Link

Colonies are of moderate growth rate. Young colonies often appear wet or glabrous but develop into dry colonies, varying from dense and granular to loose and floccose. The conidia are unpigmented so even heavily sporing cultures are white or pale cream. Microscopically, there may be large spherical heads, but reduced heads reminiscent of *Penicillium* spp. may be present. Unlike the dry conidia of most *Aspergillus* spp., the conidia of *A. candidus* readily become wetted when touched with a needle.

Fusarium solani (Mart.) Sacc.

The colony is fast growing, reaching a diameter of 30–40 mm in a week, and producing a uniform, densely floccose, aerial growth. Many strains remain white or dull cream–buff, although others develop shades of bluish–purple. Microscopically, the conidia are ovoid to kidney-shaped, 4–8×3–4 μm and are produced on long hypha-like phialides.

Fusarium oxysporum Schlecht

This species is similar to *F. solani*, but colonies are salmon pink to violet, and the conidia are produced on

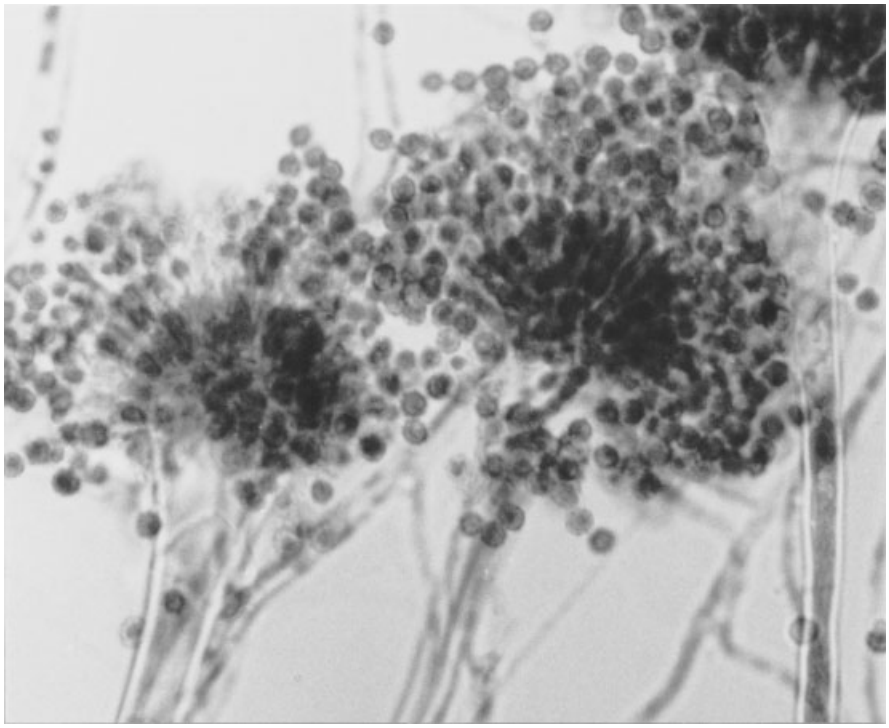

Figure 3 Aspergillus versicolor*: sporing heads showing the typical small vesicles with 2 rows of cells below the conidia*

short lateral phialides. Both species may produce smaller numbers of sickle-shaped multicellular macroconidia.

Onychocola canadensis Sigler

Unlike species of *Scytalidium*, *O. canadensis* is resistant to cycloheximide at 0.4 mg/l so it will grow on routine isolation media but shows enhanced growth on carbohydrate-rich medium. Colonies are restricted, attaining a diameter of 14–20 mm in 6 weeks at 25°C on glucose peptone agar, and may cause cracking of the agar. Typically, after 2 weeks at 25°C, colonies are more than 1 cm in diameter, yellowish–white to pale gray with a darker brownish–gray reverse. The surface is domed with abundant aerial mycelium and a cottony, velvety, or woolly texture. *O. canadensis* will grow at 37°C but is less vigorous.

Microscopy of older cultures may reveal abundant broad, pheoid hyphae up to 6.5 μm in width with few septa and with darker-brown wall thickenings; these are similar to the hyphae observed in infected nail specimens. Sporulation is slow, conidia are formed in chains from poorly differentiated, septate, hyaline hyphae 1.5–3 μm wide. Formation of conidia may be either intercalary along the length of the hyphae or in basipetal succession on lateral chains. Conidia (arthroconidia) are broadly ellipsoidal, cylindrical, or irregular in shape, and either unicellular or with a single septum, often persisting in long, branched chains. Release of arthroconidia is by dissolution (rhexolysis) of adjacent thin-walled cells or by schizolysis of adjacent conidia; the remnants of wall material may be visible on the end walls of the detached conidium (Figure 4).

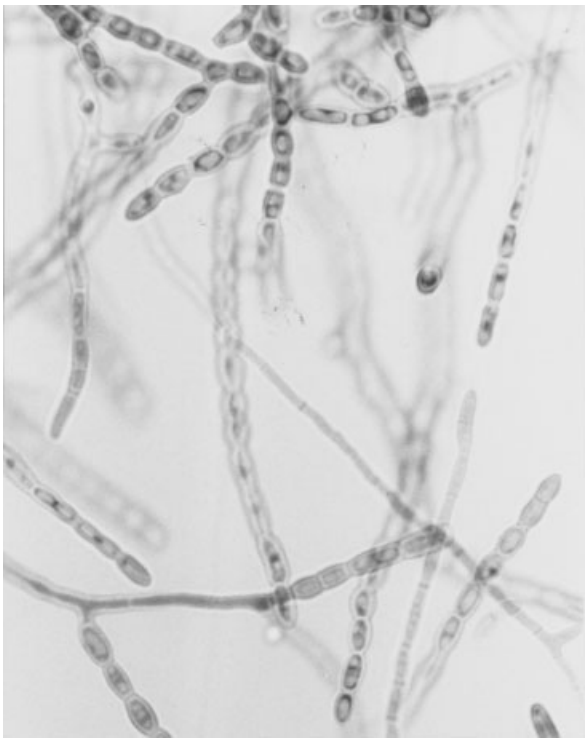

Figure 4 Onychocola canadensis*: thick-walled arthroconidia in sparsely branching chains removed from a 4-week-old culture*

Paecilomyces variotii and *P. lilacinus*

The genus is a group of saprophytes and insect parasites closely related to *Aspergillus* and *Penicillium*. The conidia are produced in unbranching chains from phialides. In some species the phialides are grouped in whorls as in *Penicillium*, but single phialides are common, as are irregular branching systems of phialides. In contrast to many *Aspergillus* spp. and all *Penicillium* spp., the conidia are not colored green. *P. variotii* produces colonies which are flat, fast growing, and with a finely powdery surface. The conidia are variable in size as they continue to grow in size as the chain of spores develops, but are generally ovoid to lozenge-shaped, 3–7 μm long (Figure 5). The other species in nails, *P. lilacinus*, produces domed, cottony colonies, which become flattened with age. The aerial growth is a pale lilac purple color. Microscopically the phialides are narrow and tightly compacted together in irregular *Penicillium* like clusters. Conidia are smaller than in *P. variotii*, mostly about 3 μm long.

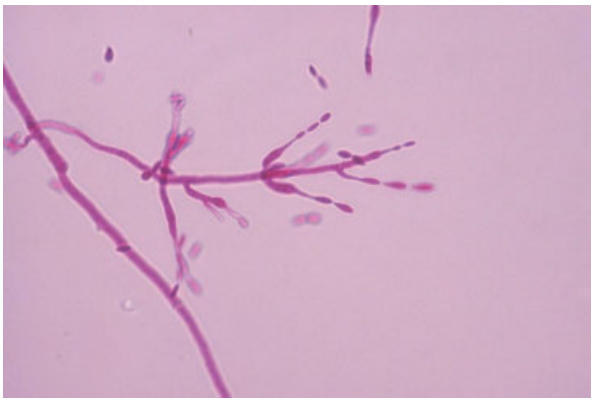

Figure 5 Paecilomyces variotii *showing slender phialides producing unbranched chains of oat-shaped cells*

Scopulariopsis brevicaulis Bainier

S. brevicaulis is an annelidic hyphomycete which will grow on cycloheximide-containing medium and forms spreading colonies, often with a raised and furrowed central area. It has a powdery surface as a result of the production of abundant conidia, and it is grayish–white at first, developing a cinnamon-colored central area on production of conidia.

Microscopy reveals an abundance of lemon-shaped, roughened conidia with truncated bases, which are produced in basipetal chains from the tips of annellidic conidiogenous cells. The annellides, which increase in length with age as each successive spore leaves a collar of wall material, are produced singly or in penicillate heads (Figure 6).

Scytalidium dimidiatum (Penz.) Sutton and Dyko (pycnidial synanamorph *Nattrassia mangiferae* (Sydow and Sydow) Sutton and Dyko)

In cultures of *S. dimidiatum*, two types of growth may be produced. These were described in detail by Campbell

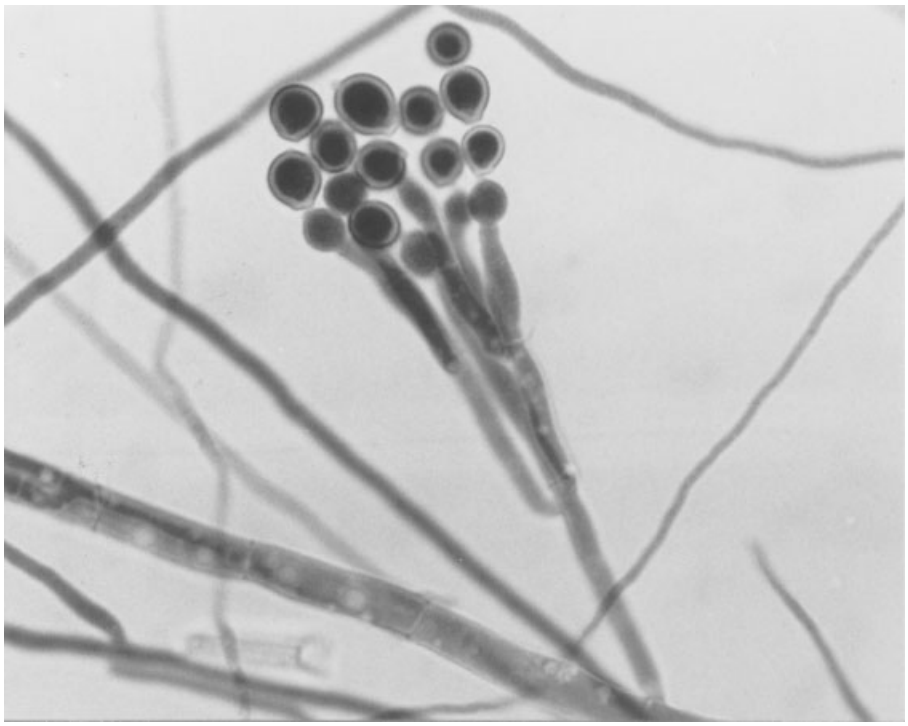

Figure 6 Scopulariopsis brevicaulis*: unbranched conidial chains, each with the youngest conidium at the base*

(1974). Type A is fast growing, filling a 9 cm Petri dish in 2–4 days with a dark-gray, floccose, aerial mycelium which becomes brownish–black after a week. A few strains show concentric zones of growth. Microscopy of this type shows a mixture of wide, brown-pigmented hyphae and narrow hyaline hyphae. Both hyphal forms are much fragmented into long-cylindrical to barrel-shaped arthroconidia, 2.5–10×2.5–7 μm, many with two cells (Figure 7). Type B is much slower growing, reaching a diameter of 2 cm in 1 week, with little aerial mycelium; the colour is gray–olive, with an irregular submerged margin. Scanty brown arthroconidia are seen on microscopy. In addition to the spores, this type also features coiled hyphae, and older hyphae may bear irregular thickenings on the outer surface of the walls. Type A was associated with immigrants from the Caribbean area, and type B with patients of Indo-Pakistani origin. In a larger series of cases, Moore (1988) found the same geographical split between the fast- (type 1) and slow- (type 3) growing strains. In this study several intermediate colonial forms (type 2) were also found.

On prolonged incubation, strains of type A may develop the pycnidial state, referred to the taxon *N. mangiferae* (Sydow and Sydow) Dyko and Sutton or its earlier synonym *H. toruloidea* Nattrass. This takes the form of hard, carbonaceous stromata, each with several multilocular pycnidia embedded inside. Each connects to the surface via an ostiole through which the pycnidioconidia are released. The pycnidioconidia are ovoid with pointed ends, 10–14×4–6 μm, and become biseptate, with the central cell darker than the end cells.

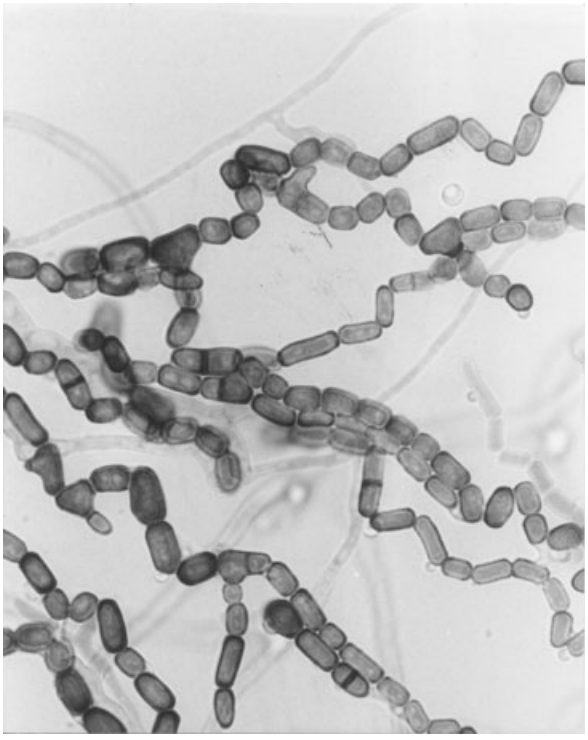

Figure 7 Scytalidium dimidiatum*: brown-walled arthroconidia formed by the irregularly timed formation of cross-walls results in some spores with two cells*

Scytalidium hyalinum Campbell and Mulder

S. hyalinum grows rapidly on glucose peptone agar or other common media at 28–32°C to produce a white, effuse, cottony, aerial mycelium. With age, a yellowish color may develop and the mycelium collapses somewhat. Microscopy shows an abundance of arthroconidia formed in chains by the disintegration of the aerial hyphae. The spores are cylindrical to ellipsoidal, mostly aseptate but some with two cells, thin-walled, smooth and hyaline, separated by septal splitting. Attempts to induce pycnidia or other conidial states have failed.

TREATMENT OF ONYCHOMYCOSIS AND DERMATOMYCOSIS CAUSED BY MOLDS

Treatment of onychomycosis due to molds is difficult and there is no consistent treatment of proven efficacy. Organisms such as *S. brevicaulis* are not susceptible in vitro to any of the agents licensed for superficial fungal infections. However, in vivo–in vitro correlation has not been established for molds and, despite high MICs in vitro, there are reports of successful treatment. It is possible that a significant number of mold infections only arise due to trauma to the nail by an underlying dermatophyte infection. In these situations it may be that the presence of the dermatophyte is masked by the overgrowth of mold. However, treatment of the underlying dermatophyte can lead to successful resolution of the mold infection. It was reported by Ellis et al. (1997) in their study on onychomycosis that the presence of a mold had no influence on the outcome of treatment with terbinafine.

Treatment of nail infections usually entails oral treatment with a systemically active agent such as terbinafine or itraconazole. Topical application of an antifungal agent, such as terbinafine, tioconazole, or amorolfine, as a paint or lacquer directly onto the nail surface, is unlikely to have the penetrative power to reach all infected tissue, although it may be useful in cases of superficial white onychomycosis. There has also been a report of successful treatment of a *S. hyalinum* onychomycosis with frequent application of amorolfine nail lacquer (Downs et al. 1999), and it may lead to higher rates of resolution when used in combination with an oral agent or following nail avulsion.

Another factor that may have some bearing on outcome of treatment of a mold infection is that oral treatment with itraconazole can lead to high tissue concentrations, particularly in keratinized tissue. Levels in skin and nail tissue may far exceed serum levels; thus

the drug may have activity against molds demonstrating relative insusceptibility in vitro. The accumulation and persistence of this drug in keratinized tissue also allows for the use of this agent as pulse therapy. The regimen suggested for pulse therapy is 200 mg twice daily for 1 week followed by a 3-week break. Two pulses may be sufficient for fingernail infections whereas three pulses are usually required to eradicate toenail infection.

A prospective, comparative parallel group, single-blind, randomized study investigated the efficacy of systemic fluconazole, griseofulvin, itraconazole, ketoconazole, and terbinafine in the treatment of 59 patients with toenail onychomycosis due to *S. brevicaulis*. Standard dosage regimens were employed and patients were evaluated for clinical and mycological cure at 12 months after the start of treatment. Terbinafine and itraconazole produced the best response rates with high levels of both clinical and mycological cure (Gupta and Gregurek-Novak 2001). A second group evaluated the efficacy of systemic itraconazole or terbinafine, topical terbinafine following nail plate avulsion, and ciclopirox lacquer in the treatment of patients with onychomycosis due to a variety of molds. Response rates were highest with *Aspergillus* spp. infections (100 percent), *Acremonium* spp. (71.4 percent), *S. brevicaulis* (69.2 percent), but only 40 percent of 26 patients with onychomycosis due to *Fusarium* spp. responded (Tosti et al. 2000).

An initial treatment with any of the systemically active antifungal agents licensed for dermatophyte infections may be beneficial in secondary mold infections, but itraconazole and terbinafine appear to be associated with the most consistent success rates. In extreme cases, it may be necessary to perform surgical removal of the nail plate or avulse the nail with a chemical application such as urease paste. However, following such treatment the nail tissue regrowth may not appear entirely normal.

Superficial candidiasis

PAUL L. FIDEL Jr AND KAREN L. WOZNIAK

Epidemiology	2	Host response against *C. albicans*	5
C. albicans as a commensal of the gastrointestinal and genitourinary tracts	3	Host defense against superficial candidiasis at anatomic sites	7
C. albicans as a pathogen of the gastrointestinal and genitourinary tracts	4	Immunotherapy	13
		Conclusion	13
		References	14

Superficial candidiasis includes infections of cutaneous or mucocutaneous tissues. *Candida albicans* is the causative agent in the majority of infections. Other *Candida* species that can cause the superficial infections include *C. tropicalis*, *C. glabrata*, *C. parapsilosis*, *C. stellatoidea*, *C. dubliniensis*, and *C. krusei* (Cann 1992). Superficial candidiasis can be acute, chronic, or recurrent. *Candida* spp. and *C. albicans*, in particular, are ubiquitous dimorphic fungal organisms that are part of the normal microflora of healthy individuals. However, they are also opportunistic pathogens that can quickly transform from harmless mucosal commensals to a highly pathogenic organism of the same tissues with significant morbidity and even mortality under the appropriate conditions (Fidel 1999).

Superficial candidiasis can include skin, oropharyngeal, gastrointestinal, vaginal, and conjunctival tissue infections. Cutaneous candidiasis usually occurs as erythematous patches on the thigh and buttocks, or as superficial infections of the hands in individuals who routinely wear plastic gloves. Mucocutaneous infections may be chronic and/or recurrent and one particular form is classified as the disorder known as chronic mucocutaneous candidiasis (CMC). These infections affect a variety of mucosal tissues, skin, and nails. Oropharyngeal candidiasis (OPC) involves infections of the buccal mucosa, gingiva, and tongue. The infections can be atrophic with erythematous lesions or pseudomembranous (thrush) with characteristic white lesions. Esophagitis is the most common form of gastrointestinal candidiasis. The second most common site of gastrointestinal candidiasis is the stomach. Vaginitis involves infections of the vaginal lumen and often the vulva as well. An estimated 75 percent of all women will experience at least one episode of acute vulvovaginal candidiasis (VVC). A separate population of women (5–10 percent) will experience recurrent VVC (RVVC) (Sobel 1988). Conjunctivitis caused by *C. albicans* infects the mucous membranes of the eye, while keratitis affects the cornea. The common superficial *Candida* infections are summarized below:

- Cutaneous
- Mucocutaneous
  - Oropharyngeal
  - Gasatrointestinal
    - Stomach
    - Esophageal
  - Vaginal
  - Conjunctival/keratitis

Host defense mechanisms that protect against *C. albicans* infections include innate resistance and acquired immunity. The relative contributions of these two systems, however, differ depending upon the site at which *C. albicans* enters the host. Innate host defenses (i.e. polymorphonuclear leukocytes, macrophages) are heavily involved in protecting the systemic circulation, antibodies (i.e. IgA, IgG) appear to play a role at both

systemic and mucosal sites, and cell-mediated immunity (CMI) (i.e. T cells, relevant cytokines) protects primarily mucosal tissues. With regard to mucosal tissues, while historically there was no distinction between different anatomic sites, there is now increasing evidence that 'not all mucosal tissues are created equal' relative to protective host defenses. Accordingly, current data show roles for several types of host responses at any one site, albeit at different levels of priority with respect to their protective capacity. This review covers the epidemiology of each superficial infection, properties of *C. albicans* as a commensal of the gastrointestinal and genitourinary tracts, properties of *C. albicans* as a pathogen causing superficial infections, and host defenses critical to protection against and susceptibility to superficial candidiasis at the various anatomic sites.

EPIDEMIOLOGY

Cutaneous/mucocutaneous candidiasis

Cutaneous infections affect the skin, whereas mucocutaneous infections affect the mucous membranes. Cutaneous candidiasis can be acute or chronic (reviewed in Odds 1988a) (Kirkpatrick 1989) and are characterized by erythema, edema, and a creamy exudate. Acute infections usually occur as a diaper rash in infants or between folds of skin in obese individuals or on the hands of individuals who routinely wear plastic gloves. The major symptoms are burning and itching. If left untreated, infections usually persist as long as the tissue remains moist. Chronic infections usually involve the feet and present with a thick layer of infected stratum corneum overlaying the epidermis.

Chronic mucocutaneous candidiasis is a heterogenous description that applies to infections involving chronic or recurrent infections of the skin, nails, and mucous membranes. The disease usually appears in the first 3 years of life, and affects males and females equally (Kirkpatrick 1984). Four types of CMC exist, including familial CMC, CMC with endocrinopathy, CMC with familial susceptibility and endocrinopathy, and CMC with onset after 10 years of age (reviewed in Ruhnke 2002). Patients usually develop oropharyngeal candidiasis followed by perianal candidiasis. Additionally, lesions appear on the scalp, torso, and extremities, and nail infections occur (Kirkpatrick 1984). Several disorders are associated with CMC, including hypoendrocrine function, autoimmune diseases, immunosuppression, hepatitis, diabetes, thymoma, dental enamel dysplasia, vitiligo, alopecia, and infectious diseases (Filler and Edwards 1993; Kirkpatrick 1994). Symptoms of CMC include disfiguring lesions on the skin and nails and dysphagia, due to ulcerative lesions on the buccal mucosa and esophagus (Kirkpatrick 1984).

Oropharyngeal candidiasis

Oropharyngeal candidiasis (OPC) involves infections of the hard and soft palate, tongue, buccal mucosa, and floor of the mouth. It presents as reddened patches (erythematous) or white curd-like lesions (pseudomembranous). Chewing and swallowing can be difficult under these conditions. Infections can be acute or recurrent, and are common in immunocompromised patients, especially those infected with the human immunodeficiency virus (HIV). OPC is also a common manifestation of CMC (reviewed in Odds 1988a) and occurs in patients with lymphoma, those undergoing steroid therapy, and in transplant recipients. Although OPC will occur under several immunocompromising conditions, it appears to be much more common in HIV-infected persons than under any other condition. In fact, OPC is often one of the first clinical signs of underlying HIV infection and will occur in 50–95 percent of all HIV-positive persons sometime during their progression to full-blown acquired immunodeficiency syndrome (AIDS) (Rabeneck et al. 1993). Thus, it is possible that a link between HIV and OPC is present that enhances susceptibility to OPC. Interestingly, highly active antiretroviral therapy (HAART) has reduced the incidence of OPC (Palella et al. 1998). This is postulated to be due both to increased immune responsiveness as well as the action of the protease inhibitors in HAART on the secretory aspartyl proteases (SAP), important virulence factors of *C. albicans* (Cassone et al. 1999; Gruber et al. 1999; Calderone and Fonzi 2001).

Gastrointestinal candidiasis

For the purposes of the discussion at hand, gastrointestinal (GI) candidiasis will be defined as infections of the esophagus, stomach, and small and large intestines. GI candidiasis is not easily recognized clinically but does occur in cancer patients who are heavily immunosuppressed and patients receiving antibiotic prophylaxis (Anaissie and Bodey 1990; Samonis et al. 1994). Esophagitis is the most common form of gastrointestinal candidiasis that occurs in later stages of immunosuppression and is considered an AIDS-defining illness (Macher 1988). It is extremely painful and can promote wasting because of the difficulty with swallowing. White plaques are usually observed similar to thrush. Complications include bleeding and perforation. Diagnosis is made on appearance of ulcers and erosions on the esophagus, and may need to be confirmed by endoscopy and biopsy of the affected site (Wheeler et al. 1987). The second most common site of GI candidiasis is the stomach where symptoms of gastritis occur. GI candidiasis is sometimes difficult to diagnose due to the lack of specific symptoms and the lack of the ability to differentiate between infectious and commensal *C. albicans*.

Vaginal candidiasis

Vulvovaginal candidiasis (VVC) affects a significant number of women predominantly in their reproductive years (Sobel 1988, 1992; Kent 1991). An estimated 75 percent of all women will experience an episode of acute VVC in their lifetime with another 5–10 percent succumbing to RVVC (Sobel 1988, 1992). Vaginitis involves infections of the vaginal lumen and often the vulva as well. Symptoms include burning, itching, soreness, an abnormal discharge, and dyspareunia. Signs include vaginal and vulvar erythema and edema. Acute VVC has several known predisposing factors including antibiotic and oral contraceptive usage, hormone replacement therapy, pregnancy, and uncontrolled diabetes mellitus (Sobel 1988, 1992; Kent 1991). RVVC is multifactorial in etiology, but is usually defined as idiopathic with no known predisposing factors in the majority of those affected (Sobel 1988, 1992). In women with RVVC, antifungal therapy is highly effective for individual symptomatic attacks, but does not prevent subsequent recurrence. There is little evidence that resistance to antifungal drugs plays a role in the pathogenesis of RVVC (Lynch et al. 1996). Instead, susceptibility to RVVC is postulated to be immune-based in that these otherwise healthy women experience repeated symptomatic episodes as a result of some immunological dysfunction or deficiency. Furthermore, it is postulated that recurrences are a result of relapse rather than reinfection since strain types of *C. albicans* tend to remain the same in women for multiple recurrences over several years (Vazquez et al. 1994). This is consistent with the fact that antifungal drugs are static rather than cidal and, as such, do not completely eliminate the organisms.

Conjunctivitis and keratitis

Conjunctivitis caused by *C. albicans* infects the mucous membranes of the eye. The eyelid and surrounding soft tissue can be swollen by adjacent tissue involved in the mycotic infection (Klotz et al. 2000). *Candida* spp. have been found in cases of ulcerative blepharitis in patients with skin atopy (Huber-Spitzy et al. 1992). Symptoms of *Candida* conjunctivitis include conjunctival erythema, cheesy discharge, and corneal ulceration. However, *Candida* can be isolated from the conjunctiva and eyelids of normal healthy individuals and remain asymptomatic (commensal) (reviewed in Klotz et al. 2000).

Keratitis caused by *Candida* spp. affects the cornea and causes ulcerative lesions on the eye (Klotz et al. 2000). The predisposing factor most often associated with *Candida* keratitis is chronic dry eye, but it can also be found in cases of trauma to the eye, abuse of corneal anesthetics, and following corneal transplant (reviewed in Klotz et al. 2000). Additionally, keratitis can be caused by wearing hard and soft extended-wear contact lenses, due to the fact that *Candida* has the ability to adhere to contact lenses and form a biofilm (Butrus and Klotz 1986; Elder et al. 1995). *Candida* keratitis presents as a small, demarcated ulcer with underlying opacity, and a granular infiltrate in the corneal epithelium and stroma can be observed. Diagnosis can be made upon microscopic examination of corneal scrapings.

General diagnosis

Together with compatible signs and symptoms, a definitive diagnosis of cutaneous and mucocutaneous *C. albicans* infection involves the demonstration of hyphae detected by microscopic analysis of tissue scraping (KOH wet mount preparation) or tissue invasion by histopathological examination. A swab culture is used to isolate the organism. Colonies are speciated in the laboratory using a variety of tests, such as germ tube formation, appearance (color) of colonies on CHROMagar Candida (Odds and Bernaert 1994; Sullivan and Coleman 1998), commercial API ID 32C or API 20C AUX (Richardson and Carlson 2002), polymerase chain reaction (PCR) (Janusz et al. 1988; Okhravi et al. 1998; Guiver et al. 2001), contour-clamped homogeneous electric field electrophoresis (CHEF) (Vazquez et al. 1992), DNA fingerprinting (Lockhart et al. 1997, 2001; Steffan et al. 1997), as well as other biochemical tests (Sood et al. 2000; Freydiere et al. 2002; Richardson and Carlson 2002).

Treatment

Nystatin, a topical polyene antifungal related chemically to amphotericin B, can be used for treatment of cutaneous candidiasis. Azoles (i.e. fluconazole, ketoconazole, butaconazole, itraconazole, etc.) are recommended for all other forms of superficial candidiasis. Antifungal drugs are highly effective for individual attacks or acute infections, but recurrence remains a problem. In fact, recurrent attacks can occur within days of cessation of treatment. Thus, in the appropriate clinical setting, maintenance therapy is encouraged. Table 1 summarizes the symptoms, diagnosis, and treatment for the various forms of superficial candidiasis.

C. ALBICANS AS A COMMENSAL OF THE GASTROINTESTINAL AND GENITOURINARY TRACTS

As stated previously, *C. albicans* is a commensal organism of the gastrointestinal and reproductive tracts. In this colonized state, individuals are considered asymptomatic carriers. It is widely recognized that as a commensal, *C. albicans* exists exclusively in the blastospore form, although it is rarely detectable in wet

Table 1 *Symptoms, diagnosis, and treatment of superficial candidiasis*

Infection	Signs/symptoms	Diagnosis	Treatment
Cutaneous	Erythema, edema, creamy exudates, burning, itching	Erythematous patches in folds of skin, KOH stain showing hyphae	Nystatin
Oropharyngeal	Reddened erythematous or white curd-like lesions, difficulty swallowing	Erythematous or pseudomembranous lesions (can be scraped), KOH stain showing hyphae	Azoles
Gastrointestinal–esophageal–stomach	Difficulty swallowing, bleeding, perforation, gastritis	Ulcers and erosions on esophagus, biopsy of lesion, KOH stain showing hyphae	Azoles
Vaginal	Burning, itching, soreness, white cottage cheese-like discharge, vuvlar edema, pruritis	KOH stain showing hyphae, culture positive, signs and symptoms	Azoles
Conjunctival/keratitis	Conjunctival edema, cheesy discharge, corneal ulceration	Corneal scraping, KOH stain showing hyphae	Topical/injected azoles

mount preparations of tissue scrapings. Instead, asymptomatic colonization is usually detected by swab culture. The most common sites showing detectable asymptomatic colonization are the rectum, oral cavity, and vagina. Although many *Candida* spp. are considered normal flora, *C. albicans* is the most common species recovered. In the oral cavity, the approximate rate of yeast carriage is 50–60 percent (Glick and Siegel 1999), but it has been reported to be as low as 2 percent and as high as 69 percent (Odds 1988b). In recent studies from our laboratory, we found that HIV-negative individuals had an oral colonization rate between 45 and 50 percent, with *C. albicans* present in 85 percent of isolates recovered. In contrast, HIV-positive individuals had an asymptomatic colonization rate in the oral cavity as high as 76 percent, with *C. albicans* present in 83 percent of isolates recovered (Leigh et al. 1998; Wozniak et al. 2002a). The distribution of *C. albicans* in the oral cavity includes the tongue, palate, and buccal mucosa. It can also be recovered from diverse areas of the gastrointestinal tract, including oropharynx, stomach, jejunum, illeum, and colon. In the stomach, *Candida* colonization ranges from 47 percent (when stomach pH is less than 3) to 70 percent (when pH is greater than 3), and species found include *C. albicans*, *C. krusei*, and *C. tropicalis* (Bernhardt and Knoke 1997). Additionally, at pH greater than 3, *C. glabrata* has been isolated from the stomach (Bernhardt and Knoke 1997). Rectal swabs were positive for *C. albicans* in 20–25 percent of healthy individuals (Odds 1988b; Soll et al. 1991). A similar proportion of normal healthy women (i.e. 20–25 percent) carry *C. albicans* in the vagina (Sobel 1988), although one study reported carriage in 40 percent of women (Soll et al. 1991), and two recent studies reported asymptomatic colonization of 13 percent (Fidel et al. 2003) and 11 percent (Bauters et al. 2002), respectively. A study of HIV-positive women reported that 37 percent were asymptomatically colonized at the vaginal mucosa, compared to 21 percent of HIV-negative high-risk women from the same study (Schuman et al. 1998b). The recovery of yeast increases during pregnancy and during select stages of the menstrual cycle, in particular when reproductive hormones are elevated (luteal phase). In contrast to colonization with *C. albicans* at mucosal sites, *C. albicans* is not considered normal flora of the skin. *C. albicans* is also infrequently isolated from water sources, soil, air, and plants, and those isolates recovered from food and beverages are considered contaminants from human and animal sources (Hasenclever et al. 1961).

Colonization with *C. albicans* at mucosal tissues is considered to occur at an early age, the organism having been acquired either by traveling through the birth canal, nursing, or from food sources. Aside from direct culture of mucosal surfaces, long-term colonization with *C. albicans* is assumed to be responsible for acquired immune responsiveness. Anti-*Candida* antibodies, circulating IgG, and mucosal IgA and IgG, can be detected in most healthy individuals (Witkin et al. 1988, 1989; Regulez et al. 1994; Wozniak et al. 2002a). Moreover, greater than 80 percent of healthy persons have positive cutaneous skin test reactivity to *Candida* antigen, and peripheral blood lymphocytes from more than 90 percent of healthy individuals proliferate in vitro to *Candida* antigen (Kirkpatrick et al. 1971; Mathur et al. 1977; Odds 1988a; Fidel et al. 1993). It is presumed that these acquired host responses in conjunction with innate resistance (i.e. polymorphonuclear leukocytes and macrophages) play a significant role in restricting *C. albicans* to mucosal surfaces in an asymptomatic commensal state.

C. ALBICANS AS A PATHOGEN OF THE GASTROINTESTINAL AND GENITOURINARY TRACTS

There are several scenarios in which *C. albicans* can convert from the harmless commensal to a serious pathogen. These include a lack of protective host defenses, expression of virulence factors by the organism, or environmental conditions that allow the yeast to overwhelm the protective host defenses.

C. albicans has several virulence factors that promote adherence and ultimately disease. Dimorphism itself is considered a virulence factor of *C. albicans* (reviewed in Calderone and Fonzi 2001). There are several environmental factors that allow *C. albicans* blastospores to transform into the more pathogenic hyphal form, the most common of which are temperature and pH. Acidic pH and temperatures below 35°C usually favor the blastospore form, whereas alkaline pH (> 6.5) and temperatures 37°C or higher favor hyphal formation. Although both forms can exist at any mucosal site, it is the hyphal form of *C. albicans* that is often observed in infected tissue. Hyphae appear to adhere and invade tissue by elaborating proteolytic enzymes. A secondary effect of dimorphism that can be associated with virulence is antigenic variation (De Bernardis et al. 1994). Antigens present on the blastospore and hyphal surface may be different and thus one or the other form may evade immune surveillance.

Aside from dimorphism, there are other components of *Candida* that are considered to be virulence factors. One virulence factor is the presence of integrin analogs on *C. albicans* that enhance adhesion to epithelial cells (Cann 1992). Interestingly, compared to non-*albicans* species, *C. albicans* has been reported to express the highest levels of the integrin analog. Another virulence factor is hyphal wall protein-1 (HWP-1), which is an adhesin that is important in attachment to human buccal epithelial cells through the action of transglutaminase (Staab et al. 2000). Other adhesins that are considered to be virulence factors include agglutin-like sequence-1 (Als1p), Als5p, and integrin-like protein-1 (Int1p) (reviewed in Calderone and Fonzi 2001). Phenotype switching, an in vitro phenomenon which involves phenotypic changes in the absence of genotypic changes, represents yet another possible virulence factor (Soll 1992, 2002). If it occurs in vivo, as predicted, it would affect both adherence and immunological escape. Also, SAPs, which are known to be involved in invasion of tissues and tissue damage, are thought to be virulence factors for *Candida* (reviewed in Calderone and Fonzi 2001; Hube and Naglik 2002) (De Bernardis et al. 1990, 1999). This seems especially true at the oral and vaginal mucosa where isolates recovered from infections have been shown to express high levels of specific SAPs (Hube et al. 1997; De Bernardis et al. 1999; Schaller et al. 1999). Additional virulence factors are the secretion of hydrolases which enhance adherence to mucosal tissues, and heat-shock proteins that bind to serum proteins and inhibit proper folding of the serum proteins as well as interactions with other proteins (reviewed in Ross et al. 1990; Matthews et al. 1998; Calderone and Fonzi 2001). More recently, other components, such as spindle assembly checkpoint component CaMad2p (Bai et al. 2002), copper and zinc-containing superoxide dismutase (Cu/Zn SOD) (Hwang et al. 2002), the transcription factor Spt3 (Laprade et al. 2002), and the two-component response regulator SSK1 (Calera et al. 2000) have been suggested as possible virulence factors for *Candida*. Finally, antimycotic drug resistance of some *Candida* spp. allows them to escape therapeutic treatment regimens.

Regardless of the level of tissue penetration that is usually quite shallow as a superficial infection, there can be large numbers of organisms associated with the tissue. It is generally considered that as a result of some change in the host, the organism grows in high enough numbers to overcome the host defenses, penetrates the tissue and begins to cause the symptoms associated with the infection. It is unclear, however, at what point in the pathway the organism converts into the hyphal form. It is postulated that the conversion begins prior to penetration and that the extension on the germ tube initiates the penetration into the tissue. Other proponents suggest that the yeast initially invades the tissue and the hyphal form occurs as a consequence of exposure to serum components as the immune cells infiltrate the tissue in an attempt to eliminate the organism. The latter is supported by the high incidence of mucosal infections caused by *C. glabrata*, an organism that does not form hyphae (Fidel et al. 1999b). Nevertheless, it is clear that both the host and the organism contribute significantly to *C. albicans* as a pathogen.

HOST RESPONSE AGAINST *C. ALBICANS*

Innate resistance

The polymorphonuclear leukocyte (PMNL) (neutrophil) is the first line of defense against *C. albicans*. The role of macrophages in defense is less clear although they readily phagocytize the yeast form of *Candida*. Anti-*Candida* activities by PMNL or macrophages can be oxidative (i.e. hydrogen peroxide, nitric oxide, superoxide dismutase) or non-oxidative (i.e. lactoferrin, lysozyme, calprotectin, defensins) (reviewed in Fidel 1999). Phagocytosis is usually required for oxidative mechanisms although there is some evidence that oxidative products can be secreted by PMNL that affect nearby fungal hyphal forms too large to be phagocytosed (Levitz and Farrell 1990).

PMNL are relatively effective as a first line of defense, providing that organisms gain access to the vasculature or that the PMNL attach to hyphae. However, PMNL function can be greatly enhanced by cytokines such as tumor necrosis factor-alpha (TNF-α), interferon-gamma (IFN-γ), interleukin (IL)-2, IL-8, and colony-stimulating factors (CSF) (Djeu 1993). Oxidative mechanisms are enhanced in the presence of serum as well. There are also both classical and alternate complement pathways that become activated by *C. albicans* which promote increased adherence to phagocytes

(Heidenreich and Dierich 1985; Edwards et al. 1986; Kozel et al. 1987).

The functional mechanisms by which monocytes and macrophages affect *C. albicans* are less well defined (reviewed in Fidel 1999). In general, once phagocytosed in vitro, killing is at least as effective as PMNLs and involves oxidative mechanisms and candidicidal molecules. Activation of macrophages with cytokines appears to increase the killing activity, although the effects appear short-lived at best. Killing of both blastospores and hyphae have been demonstrated, but the rate and efficiency depends on the source of the cells. For example, pulmonary macrophages appear to be particularly efficient against *C. albicans*.

A role for dendritic cells against fungal infections has also been suggested. Immature myeloid dendritic cells can phagocytose both yeast and hyphae of *C. albicans* (Romani et al. 2002). Recognition of yeast forms is through the mannose-fucose and complement receptor 3 (CR3) receptors, while recognition of hyphae is through the FcγR and CR3 receptors (Romani et al. 2002). Mature dendritic cells are less phagocytic than immature cells, but they have increased expression of major histocompatibility complex (MHC) class II, which leads to more efficient antigen presentation (Banchereau and Steinman 1998; Pulendran et al. 2001; Reis e Sousa 2001). Dendritic cells are also capable of directing the acquired immune response to *Candida*, depending on the form phagocytosed and the receptors used, and the type of response induced can affect whether a protective or nonprotective response is generated (Romani et al. 2002).

The activity of natural killer (NK) cells against *C. albicans* has been controversial. While a limited number of studies showed inhibition of *C. albicans* growth by murine leukocyte suspensions containing NK cells (Brummer et al. 1986; Morrison et al. 1987; Steele et al. 1999a), the general consensus is that NK cells are not effective against *Candida* (Djeu and Blanchard 1987; Arancia et al. 1995). Suffice it to say that, although inhibition of *C. albicans* can be mediated by cells from lymphoid tissue, the primary and secondary effector cells are innate, not specific, and consist of PMNLs and macrophages, respectively.

A final type of cellular innate resistance mechanism has only recently been discovered and involves epithelial cells lining the surface of mucosal tissues. Oral and vaginal epithelial cells from mice, macaques, and humans have the ability to inhibit the growth of *Candida* in vitro (Steele et al. 1999a, b; Barousse et al. 2001). The inhibition requires contact between viable epithelial cells and *Candida*, with no role for soluble factors and does not involve phagocytosis (Steele et al. 1999a, 2000). While the mechanism is not fully elucidated, the inhibition appears to be mediated by a carbohydrate moiety on viable epithelial cells (Steele et al. 2001) and is static rather than cidal (Nomanbhoy et al. 2002).

Humoral immunity

C. albicans antigens readily induce the production of immunoglobulins as evidenced by the presence of *Candida*-specific IgG in serum and IgA in mucosal secretions of healthy individuals. Thus, it might be presumed that humoral immune mechanisms are important host defenses in both the systemic circulation and at mucosal sites. However, a role for antibody-mediated immunity at mucosal sites has been controversial. A major argument against a role for humoral immunity comes from clinical observations wherein individuals with congenital or acquired B-cell abnormalities are not more susceptible to mucosal (or systemic) candidiasis than immunocompetent individuals (Rogers and Balish 1980). Other observations suggestive of a lack of a role for antibody include the following:

- levels of *Candida*-specific IgA were higher in the saliva of HIV-positive patients than in HIV-negative controls (Coogan et al. 1994; Challacombe and Sweet 1997; Millon et al. 2001)
- levels of *Candida*-specific IgA, sIgA, IgG, or subclasses did not differ in saliva of HIV-positive OPC-positive patients compared to HIV-negative OPC-negative controls (Wozniak et al. 2002a)
- women with RVVC had normal levels of *Candida*-specific IgG in serum and IgA in vaginal secretions (Kirkpatrick et al. 1971; Mathur et al. 1977; Fidel et al. 1997)
- mice protected from a secondary vaginal challenge did not have detectable levels of *Candida*-specific antibodies in vaginal secretions (Wozniak et al. 2002b)
- in vitro studies have provided little evidence that serum antibody and complement can kill *C. albicans* (Rogers and Balish 1980) despite increased phagocytosis of the organism in the presence of complement.

Despite the vast information showing little role for *Candida*-specific antibodies or at least little evidence of any deficiency in such naturally induced antibodies, there are considerable data derived from animals that support a role for *Candida*-specific IgA and IgG antibodies in protection (Cassone et al. 1995; Polonelli et al. 1996; De Bernardis et al. 1997; Han et al. 1998, 2000). These contradictory findings may be reconciled by taking into consideration a theory proposed by Casadevall (1995). He suggested that a pool of natural antibodies may consist of a mixture of protective, nonprotective, and indifferent antibodies. The type that predominates in the pool of antibodies dictates the outcome (protection versus infection). If this theory is correct, then 'protective' antibodies should be present under conditions of 'immunity' and should be identifiable and able to be isolated. Unfortunately, the lack of protection observed in the presence of normal levels of

Candida-specific antibodies suggests that 'protective' antibodies, if they exist, are in the minority of most pools examined. On the other hand, protection in animal models using 'protective antibodies' with known specificities and of a specific class and subclass, provides considerable hope for the use of these antibodies for vaccine development.

Cell-mediated immunity (CMI)

In contrast to the controversial issues regarding the role of humoral immunity against mucosal candidiasis, the role of CMI is somewhat better defined, at least as far as clinical correlations are concerned. Clinical observations support an important role for CMI in protection of mucosal tissues against invasion by *C. albicans*. The strongest evidence is that individuals with reduced or absent CMI (AIDS patients, transplantation recipients, lymphoma patients treated with T-cell immunosuppressive therapy, and patients on corticosteroid therapy) have a high incidence of mucosal candidiasis (i.e. oropharyngeal, esophageal, mucocutaneous) (reviewed in Fidel and Sobel 1994). In addition, there is a direct causal relationship between reduced *Candida*-specific CMI in the peripheral circulation and the incidence of individuals with CMC (Kirkpatrick et al. 1970, 1971). The role of T cells, however, at each respective mucosal site (i.e. oral mucosa, vaginal mucosa, GI tract) is poorly understood as are the relative roles of cells migrating from the systemic circulation into the mucosal sites versus those resident in the mucosal tissue.

The mechanisms associated with CMI against *C. albicans* appear to be dominated by $CD4^+$ T cells. Protection often correlates with delayed-type hypersensitivity (DTH), but a direct role for DTH has been difficult to assess. There have been reports where the presence of DTH did not correlate with protection (Fidel et al. 1994; Garner and Domer 1994). Nevertheless, *Candida*-specific DTH develops in vivo in the immunocompetent individual. DTH is demonstrable at an early age and likely results from early exposure to *C. albicans*. Thus, a pool of *Candida*-specific memory T cells continues to circulate in the peripheral circulation. The response is presumably initiated at the mucosal site where antigen-presenting cells such as Langerhans cells or dendritic cells process and present the antigen to locally associated T cells or transport it to the draining lymph nodes where T cells can be primed. Upon migration of the *Candida*-specific T cells to the site of antigen deposition and contact with additional processed antigen, cytokine secretion by the T cells activates tissue macrophages and signals other phagocytic cells to infiltrate the site of the insult (mononuclear infiltrate), in an attempt to eliminate or reduce the organism. The current dogma is that Th1-type responses are associated with resistance against intracellular pathogens, while Th2-type responses are associated with resistance to extracellular pathogens. However, for *C. albicans*, and in fact most medically important fungi, Th1-type responses have been associated with resistance to infection, with Th2-type responses showing an association with susceptibility to infection (Magee and Cox 1995; Romani et al. 1996; Cenci et al. 1999; Tachibana et al. 1999; Cain and Deepe 2000; Wuthrich et al. 2000).

In contrast to the role $CD4^+$ cells play in protection from *C. albicans* infections at mucosal tissues, a role for $CD8^+$ cells as an acquired host defense is unknown. To date, there has been no evidence that $CD8^+$ cytotoxic T lymphocytes (CTL) are directly involved in host defense against *C. albicans*. However, gnotobiotic mice deficient in $CD8^+$ T cells are susceptible to gastric candidiasis (Balish et al. 1996; Jones-Carson et al. 2000). Additionally, $CD8^+$ T cells have a role in suppression of CMI in candidiasis. There are numerous reports showing that $CD8^+$ T cells specific for *C. albicans* cell wall antigens, both glycoprotein and mannan, suppress DTH and lymphocyte proliferation in infected mice (Domer et al. 1989; Garner et al. 1990; Garner and Domer 1994). Suppressor or regulatory cells also appear to hinder the ability to clear the infection (Garner and Domer 1994). It appears that the downregulation of DTH includes an antagonistic function of IL-12 p40, and that the production of $CD8^+$ downregulatory T cells is dependent on the presence of IL-10, IL-4, and IFN-γ in the absence of biologically active IL-12 (Li et al. 1998; Wang et al. 1998). Additionally, naïve $CD8^+$ T cells stimulated with IL-2 inhibit the growth of *C. albicans* (Beno et al. 1995). This was first shown in cells from uninfected mice, but more recently has also been suggested clinically in persons who have had a recent episode of OPC (Colon et al. 1998). The mechanism appears to be non-MHC restricted through the action of excreted enzymes (Mathews and Beno 1993; Beno et al. 1995) and may in fact be a form of innate immunity.

HOST DEFENSE AGAINST SUPERFICIAL CANDIDIASIS AT ANATOMIC SITES

Cutaneous/mucocutaneous candidiasis

Host defense against cutaneous or mucocutaneous candidiasis involves both innate and adaptive host defenses. Innate defenses involve PMNL and monocytes/macrophages. These cells can be resident in the respective tissues or recruited to the site by chemotactic factors. The adaptive host defenses are predominantly T cells, most probably of the $CD4^+$ Th1-type cells. In cases of CMC, in vitro *Candida*-specific responses by peripheral blood mononuclear cells (proliferation and cytokine production) are reduced compared to those without CMC, suggesting some immunological defect in CMI (Kirkpatrick et al. 1971; Ruhnke 2002). In addition,

delayed skin test reactivity to *Candida* antigen is usually absent (Kirkpatrick et al. 1970; Ruhnke 2002). These reduced responses can be restricted to *Candida* or can be part of an overall reduced responsiveness to several antigens (Kirkpatrick et al. 1970, 1971). The results of studies involving experimental cutaneous disease also suggest a protective role for CMI (Wilson and Sohnle 1986). In a more recent report, in fact, the authors have described the costimulatory isoform of B7 (B7-2) as being required on antigen-presenting cells to induce a protective Th1-type response (Gaspari et al. 1998). By contrast, there is little evidence that humoral immunity has a role in protection in CMC. *Candida*-specific antibodies are present in sera and mucosal secretions of those with or without CMC (Lehner et al. 1972; Ruhnke 2002). However, aside from immunoreactivity for detection of antibodies, no studies have assessed the actual function of the antibodies present. Serum factors have been suggested as a possible source of the immunological defect(s) in patients with CMC (Valdimarsson et al. 1973; Twomey et al. 1975), in that it has been reported that *Candida*-specific carbohydrate antigens can be present and persist in the serum of those with CMC that inhibit peripheral blood lymphocyte responses (Fischer et al. 1978).

Interestingly, the immune responses against cutaneous and mucocutaneous candidiasis may involve an immune network in the epidermis termed skin-associated lymphoid tissue (SALT) as well as those infiltrating from the periphery (Singl et al. 1999). SALT includes epidermal Langerhan's cells, dermal dendritic cells, dermal T lymphocytes consisting primarily of α/β T-cell receptor (TCR)-positive cells and small numbers of γ/δ TCR^+ cells, epidermal T cells with considerably more γ/δ TCR^+ cells, keratinocytes, and microvascular endothelial cells (Bos et al. 1990).

Gastrointestinal candidiasis

Host defense against GI candidiasis has been studied primarily through the use of immunodeficient mice. Studies using both congenitally deficient and severe combined immunodeficient (SCID) mice have shown that T cells are critical for effective protection against GI candidiasis (Cantorna and Balish 1990). SCID mice were shown to be more susceptible to GI tract colonization, but were not susceptible to intravenous challenge or dissemination from the GI tract. Mice with congenital T-cell (*nude/nude*) and phagoctyic cell (*beige/beige*) deficiencies (*nu/nu, bg/bg)* developed persistent GI candidiasis, while those with only phagocytic cell deficiencies (*nu/+*, *bg/bg*) cleared *C. albicans* from the GI tract effectively. The *nu/+* mice (wild-type) responded to *Candida* antigens with IL-2 production and DTH, while *nu/nu* mice did not, suggesting the correlation between a Th1-type response and clearance of the organism. An important question, however, is what role circulating and mucosal T cells actually play in the protection. It has been shown that the mucosal tissue of the GI tract has intraepithelial lymphocytes (IEL), Peyer's patches (organized lymphoid tissue), T cells, and antigen-presenting cells that function in many types of GI infections. Much less is known, however, about the function of any of these cell populations against *C. albicans*, although Bistoni and colleagues have begun to address this issue. It was shown that Peyer's patch lymphocytes from colonized mice which went on to clear the fungus from the GI tract produced Th1, but not Th2-type cytokines in response to *Candida* antigen (Bistoni et al. 1993). Additionally, GI candidiasis appears to conform to the Th1/Th2-type immune response pattern seen in cutaneous infection and experimental systemic infections, namely that Th1-type responses are associated with resistance against infection, while Th2-type responses promote susceptibility (Magee and Cox 1995; Romani et al. 1996; Cenci et al. 1999; Tachibana et al. 1999; Cain and Deepe 2000; Wuthrich et al. 2000). The role of antibodies against GI candidiasis has not been evaluated experimentally except through early studies that showed no protection from *Candida* antibody-containing sera (Balish and Filutowicz 1991; Greenfield 1992).

Host response to esophageal candidiasis has not been studied clinically or in animal models. However, clinical observations show susceptibility to infection almost exclusively during severe T cell immunocompromised conditions (i.e. late-stage AIDS) (Macher 1988; Hoover et al. 1993; Martinez et al. 2000), suggesting that protective host defenses are intact for longer periods of time in the esophagus compared to the oral cavity, although this could also be due to less of a commensal presence of *Candida* in the esophagus. Additionally, animal models have been developed for study of esophageal candidiasis (De Repentigny et al. 2000; Walsh et al. 2000), but have been used for evaluation of chemotherapeutic treatment or fungal pathogenesis, and studies on host defense against esophageal candidiasis are still sorely needed.

Oropharyngeal candidiasis

Oropharyngeal candidiasis (OPC) occurs primarily in individuals with HIV (Nielsen et al. 1994; Sangeorzan et al. 1994; Schuman et al. 1998a; Greenspan et al. 2000). Host defense against OPC has only recently begun to be studied in greater detail due primarily to the HIV epidemic. Animal models have not been of great value in understanding the natural host defense, as the disease resolves too quickly with variable and inconsistent fungal titers in immunocompetent animals (reviewed in Samaranayake and Samaranayake 2001). On the other hand, information has accumulated from humans who

are immunocompromised. In general, most data to date suggest that $CD4^+$ Th1-type cells are critical for host defense against infection. Clinically, OPC is most common in HIV-positive persons when $CD4^+$ cell numbers drop below 200 cells/μl (Rabeneck et al. 1993; Nielsen et al. 1994; Schuman et al. 1998a; Greenspan et al. 2000). In vitro immune analyses using peripheral blood mononuclear cells (PBMC) show that cells from most individuals respond to *Candida* antigens with Th1-type cytokines. Thus, it is generally considered that susceptibility to OPC is enhanced under reduced $CD4^+$ T cells due to either a lack of Th1-type responses and/or a shift to Th2-type responses. Some early studies in HIV-positive individuals suggested that reduced Th1-type cytokine responses were responsible for OPC (Quinti et al. 1991). However, a study evaluating PBMC reactivity in HIV-negative and HIV-positive persons with or without symptomatic OPC stratified by $CD4^+$ T-cell numbers showed little to no appreciable differences in *Candida*-specific proliferation or cytokine production between the two groups (Leigh et al. 2001). In another study, no demonstrable deficiencies in clonal responses of the PBMC from such patients to a variety of antigenic peptides were shown (Kunkl et al. 1998). These results suggested that the *Candida*-specific T cells themselves were not becoming defective with immunosuppression, but that a threshold number of $CD4^+$ T cells was required to protect the oral cavity against infection by this commensal organism. Below this threshold number of cells, local immune mechanisms must function exclusively for protection. The prevalence of OPC may then depend on the status of the local immune mechanisms. Indeed, some individuals with < 200 CD4 cells/μl never have OPC while others have recurrent bouts of OPC.

Local immunity has only now begun to be studied clinically. In support of the Th1/Th2 dichotomy concept, it was recently reported that HIV-negative individuals had Th1/Th0 cytokines in their saliva, whereas HIV-positive individuals had primarily Th2-type cytokines, which were in higher concentration in those patients with OPC (Leigh et al. 1998). Interestingly, the Th2-type profile was the result of reduced Th1-type cytokines rather than increased Th2-type cytokines. Lymphocytes have also been examined in the OPC lesions and both $CD4^+$ and $CD8^+$ cells have been identified (Romagnoli et al. 1997). Other investigators have suggested that only $CD8^+$ cells were present. Data from our laboratory supports the latter observation, and, in fact, we have shown an accumulation of $CD8^+$ T cells at a considerable distance from the *Candida* located superficially at the outer epithelium (Myers et al. 2003). This cellular accumulation is not seen in those without OPC. This may suggest a role for $CD8^+$ T cells against infection, with a potential problem in cell trafficking leading to OPC. Interestingly, a murine AIDS model (MAIDS) showed a rate of 30 percent recurrent OPC in inoculated mice with a predominance of $CD8^+$ T cells recruited into the tissues (Deslauriers et al. 1997).

Studies using experimental models support a role for a combination of T cells and innate cells against OPC. Both $CD4^+$ and $CD8^+$ T cells were shown to be recruited along with macrophages into the mucosal tissue, and intraepithelial $CD4^+$ T cells persisted after resolution of the infection (Allen et al. 1994; Chakir et al. 1994). Moreover, there was a time-dependent recruitment of γ/δ TCR^+ cells that correlated with the resolution of the disease (Chakir et al. 1994; Elahi et al. 2000). Analysis of cytokines showed a role for both Th1- and Th2-type cytokines in resistance to infection depending on the strain of mice used (Elahi et al. 2000). A recent study examined cytokines in oral tissues from infected mice and found increases in IL-6, IFN-γ, and TNF-α in mice recovering from oral infection (Farah et al. 2002). However, no IL-2, 4, or 10 was detected during infection (Farah et al. 2002). As with GI candidiasis, however, little is known concerning the specific roles of mucosal versus systemic T cells in the mucosa versus circulating T cells in protection against infection. In a recent study in vivo cellular depletions were used to create immunocompromised mice. $CD4^+$ T cells, PMNL, and macrophages all appeared to be important in resistance to disease (Farah et al. 2001).

Humoral immunity, on the other hand, again does not appear to play a role in protection against or susceptibility to OPC. Early studies of *Candida*-specific antibodies in saliva of HIV-positive persons with or without OPC yielded similar or elevated levels of IgA or IgG, although in one study a reduced affinity of *Candida*-specific IgA antibodies was shown in AIDS patients (Coogan et al. 1994). There is no evidence to date, however, that a deficiency in *Candida*-specific antibodies is present in HIV-positive persons that could account for the increased prevalence of OPC (Wray et al. 1990; Millon et al. 2001). A recent comprehensive analysis of *Candida*-specific IgA and IgG in the saliva of a large number of HIV-negative and HIV-positive persons stratified by OPC status as well as $CD4^+$ T-cell numbers, which included subclass analysis, supports the earlier findings (Wozniak et al. 2002a).

Other anti-OPC mechanisms involve innate cellular defenses. PMNL appear to play a role, as neutropenic patients are susceptible to OPC (Anaissie and Bodey 1990). However, in-depth studies with PMNL in the oral cavity have not been conducted. Epithelial cells represent another cell type with potential innate function. As stated earlier, epithelial cells have been shown to inhibit the growth of *Candida* spp. in vitro by a static mechanism (Steele et al. 1999a, 2000; Nomanbhoy et al. 2002). While both oral and vaginal epithelial cells have anti-*Candida* activity via cell contact through a putative carbohydrate moiety (Steele et al. 2001), oral epithelial cells have a much increased capacity to inhibit the growth of *Candida* (up to 80 percent versus 40 percent

for vaginal cells) (Steele et al. 2000). Analysis of oral epithelial cells in HIV-positive persons showed significantly reduced activity when the cells were derived from patients with OPC compared to that from patients without OPC, potentially contributing to the susceptibility to infection (Steele et al. 2000). Additionally, epithelial cells produce both cytokines and chemokines in response to *Candida*, which may contribute to the innate and/or adaptive immune response (Steele and Fidel 2002). Thus, several lines of defense may be important for protection against OPC, many of which do not become evident until $CD4^+$ cells are reduced below the protective threshold.

Vaginal candidiasis

In contrast to the fairly well documented role for CMI by $CD4^+$ T cells against oral, gastrointestinal, and cutaneous candidiasis, the role for CMI against vaginal candidiasis has not been clear and more recently has been challenged. Thus, despite intense efforts to date, the natural protective host defenses against VVC remain poorly understood.

Studies of host defense against VVC began with clinical observations in which women with RVVC were examined for systemic *Candida*-specific responsiveness by culture of their PBMC in vitro or through skin-testing in search of DTH responses. The results over time conflicted with the results of some studies wherein it was suggested that there was a deficiency in *Candida*-specific CMI, or an antigen nonspecific deficiency, or no deficiency at all (reviewed in Fidel and Sobel 1996). Thus, these studies did little to identify an immunological deficiency, if any, in women with RVVC.

In subsequent studies, animal models have been employed to attempt to understand the natural host defense mechanisms against vaginal *C. albicans* infection. Such studies have included rat, mouse, and macaque models of vaginal candidiasis (reviewed in Fidel and Sobel 1999). All are dependent on a state of pseudoestrus for the infection to become established. The rat model has been particularly helpful in suggesting a potential role of antibodies against *C. albicans* at the vaginal mucosa. The mouse model, on the other hand, has been used primarily to study the role of CMI (reviewed in Sobel et al. 1998). The macaque model is relatively new and to date has been described with only limited immunological data (Steele et al. 1999b). Mice and rats, in contrast to macaques and humans, are not normally colonized with *C. albicans* and do not have any preexisting *Candida*-specific immunity.

Mice inoculated under pseudoestrus conditions acquire a persistent vaginal infection together with systemic Th1-type responses, as evidenced by Th1-type cytokine production in response to *Candida* antigen by lymph node cells draining the vaginal tissue, and *Candida*-specific DTH. However, this systemic Th1-type CMI or that preinduced by systemic immunization with *Candida* antigen in adjuvant did not protect mice against vaginal candidiasis (Fidel et al. 1994). Partial protection against vaginitis was achieved, however, in animals given a second inoculation following the spontaneous resolution of a primary infection in the absence of estrogen (Fidel et al. 1995b). Interestingly, suppression of *Candida*-specific systemic CMI or systemic T-cell depletion had no effect on the protection, suggesting that systemic CMI had a limited role at the vaginal mucosa in protection against vaginal candidiasis. In support of this suggestion as well, mice, either resistant or susceptible to systemic *C. albicans* infection (Hector et al. 1982), were shown to be equally susceptible to vaginitis and could all be partially protected against a second vaginal infection (Fidel et al. 1995a). These data were supported by those gathered in another study in which six different strains of mice representing four haplotypes were used (Black et al. 1999a). Finally, adoptive transfer of *Candida*-sensitized T cells into T-cell deficient (nude) mice had no effect on the course of vaginitis (Black et al. 1999b). Based on these results, it was postulated that some form of locally acquired mucosal immunity, T-cell and/or antibody-mediated, was responsible for protecting mice against vaginal *C. albicans* infection and that the vaginal mucosa had a significant level of immunological independence with little influence from systemic sources.

The independent compartmentalization concept correlates well with a clinical study showing that RVVC patients had normal levels of *Candida*-specific Th1-type CMI in the peripheral circulation (Fidel et al. 1993). It should be mentioned, however, that others have obtained data to the contrary (Corrigan et al. 1998; Carvalho et al. 2002). Nevertheless, the lack of identifiable deficiencies in systemic CMI in women with RVVC correlates with two relevant clinical observations; women with RVVC are not susceptible to CMC or other forms of cutaneous candidiasis (Sobel 1988), and women with CMC are generally not susceptible to RVVC (Odds 1988a). Thus, the immune deficiency, if any, in RVVC patients is presumed to be localized to the vagina and does not occur at the systemic level. These data were the first evidence to suggest some level of immunological independence regarding CMI host defense mechanisms at the vaginal mucosa against *C. albicans*. Further support for these observations comes from studies with HIV-infected women, who, despite the higher incidence of OPC under conditions of immunosuppression, do not get VVC any more frequently than HIV-negative women (Clark et al. 1995; White 1996; Schuman et al. 1998b; Leigh et al. 2001). Furthermore, peripheral blood lymphocyte proliferation and Th1/Th2 cytokine production in response to *Candida* antigens was relatively similar in HIV-positive women with or without symptomatic VVC (Leigh et al. 2001), similar to RVVC patients.

Subsequent studies focused on the presence of T-cell subpopulations in the vaginal mucosa. It had been established that the vaginal mucosa, while not composed of organized lymphoid tissues as the Peyer's patches in the GI tract, is immunologically competent for both CMI and T-dependent antibody production with the presence of both T cells and MHC class II^+ cells. To this end, we and others reported that vaginal lymphocytes are phenotypically distinct from those in the peripheral circulation (Nandi and Allison 1991; Fidel et al. 1996). Despite the fact that $CD4^+$ α/β TCR^+ cells predominate in the vaginal tissue, a higher percentage of γ/δ TCR^+ cells are present with few if any $CD8^+$ cells, compared to the systemic circulation. Interestingly, human vaginal lymphocytes are also phenotypically distinct in comparison to those in the peripheral circulation, but differ from mice in the types and relative proportions of cells; the human vagina has increased $CD4^+$ and γ/δ T cells but also equal numbers of $CD8^+$ T cells (Hladik et al. 1999; Fidel et al. 2001).

Studies to examine changes in vaginal T cells during experimental vaginal *Candida* infection have all shown little evidence for modulation of α/β or γ/δ vaginal T cells during either primary or secondary experimental vaginal *C. albicans* infections, and no evidence for systemic T-cell infiltration during a vaginal *Candida* infection (Fidel et al. 1999a; Wormley et al. 2001a). These results are consistent with those from immunodeficient or knockout mice (Cantorna et al. 1990; Black et al. 1999b), and correlate with the systemic immune studies in immunocompetent mice (Fidel et al. 1994, 1995a, b, c). This lack of responsiveness to *Candida* infection in mice is in direct contrast, however, to a murine model of a genital *Chlamydia trachomatis* or herpes simplex virus-2 (HSV-2) infection where $CD4^+$ T cells were shown to infiltrate readily into the vaginal mucosa in response to infection (Kelly and Rank 1997; Parr and Parr 1997). Taken as a whole, these data emphasize the uniqueness of the host vaginal response(s) against *C. albicans*. Interestingly, a study in which a dual infection with *Candida* and *Chlamydia* was studied, showed a complete independence of 'responsiveness' in the upper genital tract (*Chlamydia*) and 'lack of responsiveness' in the lower tract (*Candida*) (Kelly et al. 2001), illustrating further the complexity of immunity in the genital tract. Together these data suggested that instead of a simple lack of a role for systemic or local CMI against *C. albicans* at the vaginal mucosa, there may be some form of immunoregulation or tolerance that prohibits a more profound CMI response.

There are several pieces of evidence, both experimentally and clinically, that support immunoregulation against CMI at the vaginal mucosa. First, experimental vaginitis in δ-chain TCR knockout mice has been found to be less severe, suggestive of a tolerance role for vaginal γ/δ T cells (Wormley et al. 2001b). Evaluation of Th cytokines in the vaginal tissue homogenates from mice showed high constitutive concentrations of transforming growth factor-beta (TGF-β) in naïve mice that were increased further in estrogen-treated and/or vaginally infected mice; these same mice had low levels of other Th1- or Th2-type cytokines (Taylor et al. 2000). Clinically, TGF-β was found in fairly high concentrations in human vaginal secretions with modulations upward over the course of the menstrual cycle (Fidel et al. 2003). In addition, although Th1/Th2 cytokines are detectable in vaginal secretions of women with RVVC, there are no discernible patterns that would account for susceptibility to RVVC when comparisons were made to control women (Fidel et al. 1997). In the mouse model of infection, T cells with appropriate homing receptors for infiltration into the vaginal mucosa are reduced/lost during a vaginal *Candida* infection despite the upregulation of reciprocal adhesion molecules on the vaginal endothelium (Wormley et al. 2001b). Further supporting immunoregulation, a T-cell-derived antigen-binding molecule (TABM) has been identified in serum of RVVC patients, and to a lesser extent in control women, that can become associated with TGF-β and inhibit *Candida*-specific peripheral blood leukocyte (PBL) proliferation and cytokine production (Little et al. 2000). Finally, despite some preliminary evidence that the intravaginal challenge of normal healthy women with *Candida* antigen stimulated Th1-type cytokine secretion in vaginal lavages 16–18 hours post-challenge (Fidel et al. 1997), the results of a more recent study in which responsiveness to the antigen in a large number of women was tested during different stages of the menstrual cycle showed no evidence of immune responsiveness (Fidel et al. 2003). Thus, there is convincing evidence that immunoregulation or tolerance is functioning at the vaginal mucosa and that it inhibits the ability of *Candida*-specific systemic CMI to reach the vaginal mucosa.

The rat model, used primarily to study humoral immunity, was also used to evalulate CMI (De Bernardis et al. 2000). The progression of infection, however, is quite different in the rat than the mouse, in that spontaneous resolution occurs within a 3-week period in the rat. Consistent with this property is the fact that T cells could be demonstrated infiltrating the vaginal mucosa following infection, and Th1-type cytokines were produced and secreted into vaginal secretions. In addition, in contrast to data obtained from the mouse model of vaginitis, a recent study in the rat model showed that passive transfer of both $CD4^+$ and $CD8^+$ T cells from previously infected rats accelerated clearance of *Candida* in the vagina of naïve animals (Santoni et al. 2002). Also, the $CD4^+$ T cells were more effective at clearance than the $CD8^+$ T cells, suggesting that, in the rat model, vaginal lymphocytes, especially $CD4^+$ T cells, are important in clearance of *Candida* from the vagina (Santoni et al. 2002). Thus, the rat, in contrast to the mouse and human, may exemplify what

would occur in response to infection in the absence of immunoregulation.

The role of humoral immunity in recovery from vaginitis is equally controversial. Immunoglobulins are clearly present in vaginal secretions, including *Candida*-specific antibodies (IgG and IgA) (Witkin et al. 1988, 1989; Regulez et al. 1994). Interestingly, though, B cells are a minor constituent of the mouse, rat, or human vaginal mucosa (Parr and Parr 1991). In contrast to other mucosal sites, IgG antibodies predominate over IgA antibodies, at least on the basis of total immunoglobulin (Fidel et al. 1997; Kutteh et al. 1998). Despite that, clinical studies show that serum IgG and vaginal IgG and IgA are similar in women with RVVC (symptomatic or in remission) and healthy control women with no history of RVVC (Kirkpatrick et al. 1971; Mathur et al. 1977; Fidel et al. 1997). Experimentally, similar results were observed in infected and uninfected rhesus macaques, including the predominance of vaginal IgG over IgA immunoglobulins (Steele et al. 1999b). In addition, in a mouse model of vaginal infection, *Candida*-specific IgA and IgG were not detectable in lavage fluids of animals protected against secondary challenge, suggesting little or no protective role for *Candida*-specific antibodies against the murine vaginal infection (Wozniak et al. 2002b). While these experimental and clinical observations largely fail to support a role for antibody against candidiasis, there are studies in rodents that indicate a protective role for humoral immunity in experimental vaginal candidiasis. Pollonelli and colleagues showed that rats given an intravaginal immunization using antibodies that neutralized the anti-*Candida* activity of a yeast killer toxin were protected against a vaginal infection (Polonelli et al. 1994). The protection was found to be associated with rising vaginal titers of anti-idiotypic IgA antibodies that could transfer protection passively to unimmunized rats. Interestingly, killer toxin anti-idiotypic-like antibodies were also detected in women with symptomatic vaginitis (Polonelli et al. 1996). Similarly, Cassone and colleagues (Cassone et al. 1995; De Bernardis et al. 1997) have shown that a primary *C. albicans* vaginal infection in estrogen-treated rats induced anti-mannan and anti-aspartyl IgA antibodies in vaginal secretions, and that those antibodies appeared to protect the same rats against a secondary vaginal infection. Moreover, recipient rats treated intravaginally with vaginal fluids from primary-infected rats were protected. In a follow-up study, vaginal lymphocyte analysis during primary or secondary vaginal *C. albicans* infections in rats revealed an increase in B cells in the tissue (De Bernardis et al. 2000). Successful protection against vaginitis in the presence of these IgA antibodies could reflect 'protective' antibodies based on the Casadevall concept of nonprotective, protective, and indifferent antibodies (Casadevall 1995). In support of this, Cutler and colleagues have shown that two different 'protective' antibodies specific for mannan (IgM and IgG3) protect mice against *Candida* vaginitis when given either locally or systemically (Han et al. 1998, 2000). Taking this into account, one might speculate that when antibodies are detected clinically that do not appear to have a protective effect, indifferent or unprotective antibodies may predominate in the antibody pool. If, indeed, there is some precedent for this, it appears to be the norm rather than the exception.

Innate immunity appears to play a significant role in protection against vaginitis as well. This was initially predicted based on a leukocytic infiltrate of predominantly PMNL that is often observed in vaginal lavage fluid of infected animals. These leukocytic cells are usually associated with or attached to the hyphae and/or sheets of epithelial cells. On the other hand, when this infiltrate is present during infection it does not correlate with lower vaginal fungal burden (Fidel et al. 1999a; Saavedra et al. 1999). Furthermore, this leukocytic infiltrate is generally not observed in clinical cases of *Candida* vaginitis. Although PMNL and macrophages are potential candidates for anti-*Candida* innate resistance and are present at or near the vaginal mucosa, Balish and colleagues (Cantorna et al. 1990) showed that animals with the beige mutation, which are immunodeficient in phagocytic cells (*bg/bg*), were not more susceptible to a natural *C. albicans* infection under non-estrogenized conditions. Two more recent studies addressed the specific role of PMNL during experimental vaginitis. The results indicated that depletion of PMNL under estrogen- or non-estrogen-treated conditions had no effect on vaginal fungal burden (Black et al. 1998; Fidel et al. 1999a), suggesting that PMNL do not play a significant role against *C. albicans* in the vagina despite their presence in the vaginal lumen during some experimental infections. Perhaps this reflects their inability to function against *C. albicans* in the vaginal microenvironment compared to their ability to function well in blood or tissue culture. It might reflect immunoregulatory activity as well. Alternatively, the presence of PMNL during an infection might not represent a response to the yeast, but simply reflect their normal presence during the diestrus stage of the menstrual cycle (every 2 days in mice) when they are deployed to phagocytize the apoptotic squamous epithelial cells from the estrus (2-day cycle) stage.

As mentioned above, vaginal epithelial cells represent a potential innate anti-*Candida* host defense mechanism. This has been shown for both mouse, macaque, and human cells (Steele et al. 1999b, 2000; Barousse et al. 2001). As described earlier, the anti-*Candida* activity mediated by a putative carbohydrate moiety inhibits rather than kills the *Candida* (Nomanbhoy et al. 2002), but vaginal cells are not as effective as oral epithelial cells (Steele et al. 2000). If these cells are important as an innate mechanism, less activity by vaginal cells may reflect a higher prevalence of vaginal versus oral candidiasis when both tissues are colonized

Table 2 *Host defenses against superficial* Candida *infections*

Host defense mechanism	Site of infection			
	Cutaneous	GI[a]	Oral	Vaginal
Innate				
PMNL[b]	+[d]	– –	+/?	– –/?
Macrophage	+	– –	– –	– –

Cell-mediated				
$CD4^+$ T cells (Th1)	+++	+++	+++	–/?
$CD8^+$ T cells	– –	+/?	++	– –

a) Gastrointestinal.
b) Polymorphonuclear leukocytes.
c) Natural killer cells.
d) Symbols: + to +++ indicates level of activity from weakly positive (+) to strongly positive (+++); +/–? indicates variable activity, if any; +/? indicates probaby activity, but unknown at present; – –/? indicates probably negative activity, but unknown at present; – – indicates negative activity; ? indicates unknown.

(Steele et al. 2000). Interestingly, a recent study in humans showed that while the vaginal epithelial cell-mediated anti-*Candida* activity was not different at the various stages of the menstrual cycle, it was significantly reduced in women with a history of RVVC (Barousse et al. 2001). Thus, reduced epithelial cell anti-*Candida* activity may represent, in part, a local immune deficiency associated with RVVC.

Table 2 summarizes the various host defenses against each form of superficial candidiasis with what is known and what is still questionable.

IMMUNOTHERAPY

In addition to antifungal drugs available, new treatment strategies are being explored, especially in the case of azole-resistance (Walker et al. 2000; Mathema et al. 2001; Ferris et al. 2002) and the appearance of infections by non-*albicans* species that are intrinsically azole resistant (Sobel 1998; Fidel et al. 1999b; Abu-Elteen 2001). One goal of studying host defense is to design possible immunotherapeutic strategies to treat or prevent infection. For example, antibodies directed at SAPs, mannoproteins, mannan, and mannoprotein extract have been proposed as potential treatments and vaccine candidates (reviewed in Magliani et al. 2002). Intravaginal and intranasal immunization using mannoprotein MP65 and Sap2 have both proved to be protective in a rat model of vaginal candidiasis (De Bernardis et al. 2002) and a mannan-specific antibody was protective against a murine vaginal infection (Han et al. 2000). Additionally, anti-idiotypic (Id) vaccination and anti-Id therapy against the yeast killer toxin receptor (KTR) have been described for both systemic and mucosal *Candida* infection (reviewed in Magliani et al. 2002). Monoclonal and recombinant rat and mouse antibodies to the KTR (mKAb and rKAb) have been produced and can kill *C. albicans* in vitro (Magliani et al. 1997; Polonelli et al. 1997). In humans, *Streptococcus gordonii*, which is a commensal organism of the vaginal mucosa, has been engineered to secrete rKAb, and this has been shown to be as effective as fluconazole treatment against vaginitis in the rat model (Beninati et al. 2000). Recently, protease inhibitors used for treatment of HIV have been shown to reduce the incidence/occurrence of OPC in HIV-positive individuals (Cassone and Cauda 2002). This is thought to be mediated by inhibiting SAPs, which are a major virulence factor and are important in invasion and tissue damage (reviewed in Hube and Naglik 2002) (De Bernardis et al. 1990, 1999). In a clinical study that examined OPC following treatment with protease inhibitors, a reduction in OPC cases as well as a reduction of the presence of SAPs in the saliva of treated patients was observed (Cassone et al. 2002). Furthermore, in the case of vaginitis, overcoming immunoregulation by gene therapy, administration of cytokines, or use of antibodies against immunoregulatory cytokines may be potential methods of immunotherapy. Alternative treatments for candidiasis are promising and may be used to treat antifungal drug-resistant infections.

CONCLUSION

In summary, superficial candidiasis includes several types of infections, including cutaneous, oropharyngeal, gastrointestinal, vaginal, and ocular. Infections at each site are accompanied by unique signs and symptoms and affect different groups of individuals. Protective host defenses against infection at each anatomic site are independent/compartmentalized, and quite distinct, with

some sites revealing mechanisms consistent with the dogma of $CD4^+$ Th1-type CMI as the main protective mechanism, and other sites, particularly the vaginal mucosa, challenging this dogma. In addition, innate immunity appears to be playing more of a role than previously thought, while humoral immunity is still considered controversial. Finally, immunotherapeutic strategies developed as a result of the research efforts appear promising, with more strategies predicted as additional immune mechanisms against superficial candidiasis are uncovered.

Oculomycosis

PHILIP A. THOMAS AND P. GERALDINE

Etiologic agents of oculomycoses	1	Intraocular mycoses	45
Fungal infections of the orbit	18	Fungal ocular infections after ophthalmic surgical procedures	55
Mycotic infections of eyelids	24	Ophthalmic mycoses associated with AIDS	56
Mycotic dacryocanaliculitis	26	Ophthalmic mycoses associated with ocular biomaterials	57
Mycotic dacryocystitis	26	Acknowledgments	60
Mycotic dacryoadenitis	27	References	60
Mycotic conjunctivitis	27		
Mycotic keratitis (keratomycosis)	28		
Mycotic scleritis	44		

Opportunistic fungal infections that occur in the eye and its associated structures are collectively termed 'oculomycoses.' Until about 30 years ago, instances of oculomycosis were sufficiently infrequent to justify single case reports in the ophthalmic literature if the etiology of the disorder could be conclusively established by culture (Wilson and Ajello 1998). However, such infections are being increasingly recognized as important causes of morbidity and blindness; certain types of oculomycoses may even be life threatening (Yohai et al. 1994; Levin et al. 1996). The cornea is the site most frequently affected (Srinivasan et al. 1991), but the orbit, lids, lacrimal apparatus, conjunctiva, sclera, and intraocular structures may also be involved.

Fungal infections of the eye affect the orbit and the eyeball (globe) itself; infections of the globe manifest as external ocular or intraocular infections.

ETIOLOGIC AGENTS OF OCULOMYCOSES

By 1998, some 105 species in 56 genera of fungi had been reported as causes of mycotic keratitis and other oculomycoses (Wilson and Ajello 1998). Since the publication of the previous edition of this book, other species and genera of fungi have been reported as ophthalmic pathogens, including *Chrysosporium parvum* (Wagoner et al. 1999), *Metarhizium anisopliae* var. *anisopliae* (de Garcia et al. 1997), *Phaeoisaria clematidis* (Guarro et al. 2000), and *Sarcopodium oculorum* (Guarro et al. 2002). Unfortunately, it may be difficult to distinguish between true ophthalmic pathogens and organisms from the environment that are inadvertently introduced into specimens during or after collection (D'Mellow et al. 1991). Hence, certain criteria need to be satisfied before a fungal strain isolated from an ocular specimen can be considered significant; this is especially important when reporting fungal genera or species that have not been previously implicated in ocular infections.

McGinnis (1980) applied strict criteria to evaluate more than 300 reports pertaining to human fungal infections published in the literature from the late 1940s to the beginning of 1979. A report was considered to be acceptable when:

- an adequate clinical history was presented that suggested a mycotic infection
- the fungus was seen in the clinical specimens
- the morphology of the fungus in the clinical specimens was compatible with the reported etiologic agent
- there was adequate evidence that the fungus was identified properly.

The assessment included reports on 60 species in 30 genera of fungi isolated from ophthalmic infections, principally keratitis, but only reports pertaining to 32 species in 19 genera of fungi satisfied the strict criteria to be considered acceptable. In this chapter, an attempt has been made to apply these and similar criteria (Thomas 2003) to assess the significance of the fungal genera and species that have been reported as pathogens in different parts of the eye (Tables 1, 2 p. 6, 3, p. 8, and 4, p. 9). In vitro susceptibility data pertaining to various species of fungi that have been implicated as causes of ocular infection, and derived from studies performed by a method approved by the National Committee for Clinical Laboratory Standards (NCCLS) are also presented (Sutton et al. 1998). It should be noted that the clinical relevance of these data to the therapy of ocular fungal infections, especially when topical antifungals are used, is uncertain. It is also not clear whether these data can be used as a guide to therapy.

There appear to be variations in the genera and species of fungi reported as causes of oculomycoses, depending on the geographical location and the time period. Up to 1962, most published reports on mycotic keratitis had cited species of *Aspergillus* as the causative organisms (Gingrich 1962); since that time, however, species of *Fusarium* have been reported as frequent causes of mycotic keratitis (Nelson et al. 1994; Thomas 1994, 2003). In the first half of a 9-year study on microbial keratitis in South Florida, nine strains of *Candida albicans* were isolated, but only one in the second half (Liesegang and Forster 1980). In the period from 1969 to 1977, *Fusarium solani* was the commonest fungal isolate from patients with keratitis in South Florida (Liesegang and Forster 1980) whereas from 1982 to 1992, *Fusarium oxysporum* was the commonest isolate (Rosa et al. 1994). Although *Fusarium solani* is apparently the commonest cause of mycotic keratitis in many parts of the world (Rosa et al. 1994; Srinivasan et al. 1997), species of *Aspergillus* have predominated in many reports from the Indian subcontinent (Srinivasan et al. 1991; Upadhyay et al. 1991; Dunlop et al. 1994; Thomas 1994). *Candida albicans* is a frequent cause of keratitis in temperate regions, including the northern United States (Thygeson and Okumoto 1974; Chin et al. 1975; Tanure et al. 2000), but is infrequently reported from tropical and subtropical regions (Rosa et al. 1994; Thomas 1994; Srinivasan et al. 1997). The reasons for these variations are not clear.

Hyaline filamentous fungi

Species of *Fusarium*, widespread saprobic or parasitic organisms that grow on decaying vegetation and various parts of wild and cultivated plants, also cause important plant diseases, particularly in major crops (Cuero 1980). These fungi are believed to account for at least one-third of all reported cases of mycotic keratitis in tropical and subtropical zones (Srinivasan et al. 1997; Gopinathan et al. 2002; Leck et al. 2002); they have also been reported to cause intraocular infections (Pflugfelder et al. 1988; Patel et al. 1994; Glasgow et al. 1996; Goldblum et al. 2000; Sponsel et al. 2002; Verma and Tuft 2002) and scleritis (Moriarty et al. 1993). *Fusarium solani* is the species most frequently isolated from ocular infections, other species reported being *Fusarium dimerum*, *Fusarium episphaeria*, *Fusarium moniliforme*, *Fusarium nivale*, and *Fusarium oxysporum* (Rebell and Forster 1980; Gonawardena et al. 1994; Rosa et al. 1994; Gopinathan et al. 2002; Vismer et al. 2002). In ocular samples, *Fusarium* spp. appear as septate, hyaline, branching hyphae (2–4 μm in diameter). Adventitious sporulation (the formation of conidia in tissues) may also occur; the conidia of *Fusarium* spp. are generally seen to be larger than those of *Paecilomyces* spp. (Liu et al. 1998). In culture, species of *Fusarium* exhibit distinctive, septate, large, banana-shaped macroconidia, with apical and basal cells (Figure 1, p. 10), occurring on sporodochia. This sporodochial type often mutates, with an associated loss of virulence, giving rise to either a mycelial type or a pionnotal type (Toussoun and Nelson 1976). Species of *Fusarium* are notoriously resistant to antifungal agents in vitro. At one reference laboratory, only 25 percent of isolates of *Fusarium solani* were found susceptible to amphotericin B in vitro, while none of the isolates tested was susceptible to flucytosine, fluconazole, itraconazole, ketoconazole, or miconazole, when tested by the NCCLS method (Sutton et al. 1998).

Fungi of the genus *Aspergillus* abound in the environment worldwide, thriving on various substrates, including corn, decaying vegetation, and soil. These fungi are also found commonly in hospital air (Leenders et al. 1999); an outbreak of ocular aspergillosis following cataract surgery was traced to ongoing hospital construction, with probable wide dispersal of conidia of *Aspergillus* spp. (Tabbara and al-Jabarti 1998). *Aspergillus* spp. are important causes of keratitis following occupational trauma (Upadhyay et al. 1991; Dunlop et al. 1994; Gopinathan et al. 2002) or surgery (Heidemann et al. 1995; Sridhar et al. 2000a) in both tropical and temperate zones of the world. Species of *Aspergillus* have also been implicated in dacryocystitis (Levin et al. 1996; Kristinsson and Sigurdsson 1998), exogenous endophthalmitis (Tabbara and al-Jabarti 1998), endogenous endophthalmitis (Weishaar et al. 1998), orbital lesions (Kronish et al. 1996; Levin et al. 1996; Johnson et al. 1999), and scleritis (Bernauer et al. 1998). While *Aspergillus fumigatus* is the most commonly isolated species, *Aspergillus flavus*, *Aspergillus terreus*, and *Aspergillus sydowii* have also been reported as etiologic agents in ocular infections (Rippon 1988; Sutton et al. 1998). In ocular samples, species of *Aspergillus* manifest as

a) C, conjunctiva; CO, cornea; E, endophthalmitis; EL, eyelid; LS, lacrimal system; O, orbit and optic nerve; S, sclera; U, uvea.
b) a, microscopy and culture positive, reliable identification; b, deemed accepted by McGinnis (1980).
c) 1, not listed in Medline; 2, deemed questionable by McGinnis (1980); 3, details of identification inadequate.
d) Identified as *Drechslera spicifera*.
e) Isolated from a Percheron cross horse.
f) Identified as *Wangiella dermatitidis*; inoculation into animal cornea reproduced disease.
g) Identified as *Drechslera rostrata*.

septate, hyaline, branching hyphae, 3–6 μm wide, which exhibit parallel walls and radiate from a single point (Figure 2, p. 10), and which are smaller than the hyphae of zygomycetes (Liu et al. 1998); dichotomous (45°) branching may occur (Figure 2), and although widely believed to be pathognomonic of *Aspergillus* spp., may be mimicked by *Pseudallescheria boydii* (anamorph *Scedosporium apiospermum*) in ocular samples (McGuire et al. 1991). Identification of the genus *Aspergillus* in culture depends on the morphology of its asexual reproductive structures; the conidiophore, with its swollen terminal end, is surrounded by flask-shaped sterigmata, each of which produces long chains of coccoid conidia that radiate out from the terminal end. Identification of the species involved is important since different species may exhibit differing susceptibilities to antifungals. For example, in vitro, 95 percent of isolates of *Aspergillus fumigatus* were found susceptible to amphotericin B, 97 percent to itraconazole, 92 percent to ketoconazole, 50 percent to miconazole, and none to fluconazole or flucytosine; by contrast, 67 percent of isolates of *Aspergillus flavus* were found to be susceptible to amphotericin B, 98 percent to itraconazole, 100 percent to ketoconazole and miconazole and none to fluconazole or flucytosine, while only 13 percent of strains of *Aspergillus terreus* were reported susceptible to amphotericin B (Sutton et al. 1998). These data suggest that different species of *Aspergillus* show varying degrees of susceptibility to amphotericin B but are generally susceptible to the imidazoles and triazoles (except fluconazole).

Scedosporium apiospermum (teleomorph *Pseudallescheria boydii*), which is found in soil, sewage, and polluted water, has been reported to cause severe ocular infection following trauma during agricultural work or by polluted water, or following immunosuppression (Taravella et al. 1997). There is unequivocal evidence to implicate *Scedosporium apiospermum* as a cause of endogenous or exogenous endophthalmitis (McGuire et al. 1991; Pfeifer et al. 1991; McKelvie et al. 2001), keratitis (Bloom et al. 1992; Sridhar et al. 2000b; Tanure et al. 2000; Diaz-Valle et al. 2002; Wu et al. 2002; Saracli et al. 2003), orbital infections (Anderson et al. 1984; Nunery et al. 1985; Jones et al. 1999), and scleritis (Moriarty et al. 1993; Taravella et al. 1997). Another species, *Scedosporium prolificans*, which was first described as a human pathogen in 1984, has been reported to cause sclerokeratitis (Sullivan et al. 1994; Kumar et al. 1997). In infected tissue, *Scedosporium apiospermum* and *Scedosporium prolificans* resemble other hyaline filamentous fungi in having septate, hyaline, branching hyphae, 2–4 μm wide. In culture, *Scedosporium apiospermum* forms white to pale or dark gray, floccose colonies on glucose peptone agar after one week (Figure 3a, p. 10). Microscopic morphology is characterized by abundant yellow to pale brown oval conidia (with a scar at the base) formed from single or branched long slender annellides (Figure 3b, p. 10),

and sometimes aggregated into bundles (*Graphium* state); ascocarps are sometimes present. *Scedosporium prolificans* grows more slowly, forming oval conidia (frequently in groups) from short annellides, with inflated bases and narrow tapering tips. The correct identification of the species, with confirmation by DNA sequencing if warranted (Guarro and Gené 2002), is important in view of differing susceptibilities to different antifungals. In vitro susceptibility testing by the NCCLS method revealed that all isolates of *Scedosporium apiospermum* were susceptible to miconazole, 95 percent to ketoconazole, 77 percent to fluconazole, and 58 percent to amphotericin B; by contrast, two of nine isolates of *Scedosporium prolificans* were found to be susceptible in vitro to miconazole, whereas all isolates tested were resistant to amphotericin B, flucytosine, itraconazole,

ketoconazole, and fluconazole (Sutton et al. 1998). Again, the relevance of these data to the therapy of oculomycoses is uncertain.

Species of *Paecilomyces* are found worldwide in soil and decaying vegetation. They may also contaminate sterile solutions and culture media, since they are resistant to most of the common sterilizing procedures (Castro et al. 1990). Many of the documented infections by *Paecilomyces* spp. in the eye and associated structures have followed surgical procedures (Castro et al. 1990). The species implicated in human infections are *Paecilomyces lilacinus*, *Paecilomyces variotii*, and *Paecilomyces marquandii* (Castro et al. 1990; Sutton et al. 1998). Documented ocular infections include endophthalmitis (Pettit et al. 1980; Okhravi et al. 1997), intralenticular infection (D'Mellow et al. 1991), keratitis (Kozarsky et al. 1984; Gordon and Norton 1985; Starr 1987; Legeais et al. 1994), and orbital infection (Agrawal et al. 1979). Keratitis due to *Paecilomyces lilacinus* frequently fails to respond to medical therapy, necessitating surgery, and endophthalmitis due to this fungus

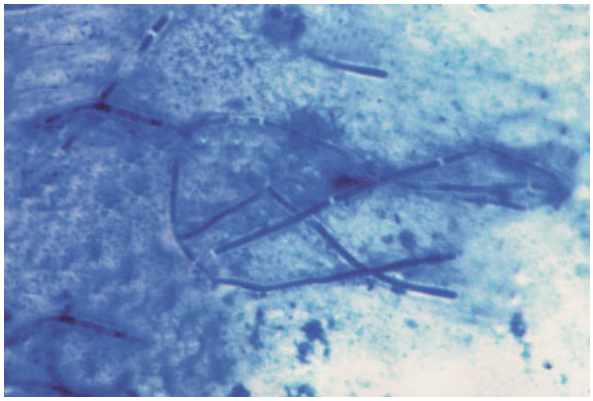

Figure 2 *Photomicrograph of septate, regular hyphae of* Aspergillus flavus *in corneal scrape material; dichotomous branching seen. Lactophenol cotton blue stain; magnification ×400*

Figure 3 (a) *Macroscopic appearance of* Scedosporium apiospermum *(7-day-old growth) on Sabouraud glucose neopeptone agar.* **(b)** *Microscopic morphology of* Scedosporium apiospermum *(7-day-old culture, Sabouraud glucose neopeptone agar). does not respond to amphotericin B (Scott et al. 2002). In infected tissue, species of *Paecilomyces* exhibit septate, hyaline branching hyphae (2–4 μm wide), which are indistinguishable from those of other agents of hyalohyphomycosis. However, abundant adventitious sporulation frequently occurs, and has been reported from samples of patients with keratitis; adventitious conidia are subglobose to very short ellipsoidal, and this feature may help in identification and selection of appropriate antifungal therapy (Liu et al. 1998). Culture is essential to identify the causal agent. In culture at 25–30°C, *Paecilomyces lilacinus* grows rapidly; the colonies are initially white in color but gradually take on a lilac–lavender hue. Culture mounts reveal flask-shaped phialides with a swollen basal portion tapering in a long distinct neck; the conidiogenous cells are borne singly, in whorls or in penicillate heads. Accurate species identification is important when dealing with *Paecilomyces*

infection since *Paecilomyces lilacinus* and *Paecilomyces marquandii* are highly resistant to polyene antifungals (amphotericin B, natamycin) and to flucytosine and susceptible to imidazoles (clotrimazole, ketoconazole, econazole, miconazole), whereas *Paecilomyces variotii* is almost universally susceptible to amphotericin B and flucytosine (Castro et al. 1990; Sutton et al. 1998).

Species of *Acremonium* are ubiquitous, being found in abundance in the soil and air (Guarro et al. 1997). *Acremonium atrogriseum*, *Acremonium kiliense*, and *Acremonium potronii* have been reported as causes of endophthalmitis (Weissgold et al. 1996; Guarro et al. 1997) and keratitis (Fincher et al. 1991; Mino de Kasper et al. 1991; Vajpayee et al. 1993; Chander and Sharma 1994; Read et al. 2000). In infected tissue, septate, hyaline, branching hyphae (2–4 μm wide) are seen; adventitious sporulation may occur (Liu et al. 1998). In culture on glucose peptone agar at 30°C, colonies are flat, smooth, gray to orange, and rapidly growing, attaining a diameter of 50 mm in 1 week; conidiophores are long, straight and slightly tapering, while conidia are ellipsoidal and accumulated in slime balls (Campbell et al. 1996).

Arthrographis kalrae is an ascomycetous filamentous fungus that is widespread in decaying plant material and in the soil. McAleer et al. (1988) reported the isolation of this fungus in two corneal scrapings taken from a patient with a corneal ulcer. Perlman and Binns (1997) reported the isolation of this fungus from corneal lesions in a contact lens wearer, although the patient was believed to have acquired the infection while not wearing the lens; although there was no response to topical natamycin 5 percent, the keratitis ultimately resolved with hourly topical 0.15 percent amphotericin B and daily oral ketoconazole 100 mg. Interestingly, this isolate of *Arthrographis kalrae* was reported to be susceptible to ketoconazole, itraconazole, and amphotericin B, but resistant to natamycin. Reported minimal inhibitory concentrations for *Arthrographis kalrae* are 0.5 μg/ml amphotericin B, 0.06 μg/ml itraconazole, and 0.5 μg/ml ketoconazole (Sutton et al. 1998). Colonies of *Arthrographis kalrae* on potato flakes agar at 25°C are rather slow-growing. Microscopy reveals septate hyaline hyphae; arthroconidia formed from short, branched or unbranched conidiophores are one-celled, hyaline, and rectangular (Sutton et al. 1998).

Fungi of the genus *Cylindrocarpon* are soil fungi and are rarely associated with human disease. *Cylindrocarpon lichenicola*, previously known as *Cylindrocarpon tonkinensis* or *Cylindrocarpon tonkinense*, has a wide geographical distribution, but occurs frequently in tropical climates, where it has a wide host range for woody post-harvest fruit invasion (de Hoog and Guarro 1995). In experimental rabbit eyes, *Cylindrocarpon tonkinense* was found to produce as severe a corneal infection as did *Fusarium solani* (Ishibashi et al. 1986). A literature survey on human keratitis due to *Cylindrocarpon lichenicola* revealed only three cases (Laverde et al. 1973; Matsumoto et al. 1979; Mangiaterra et al. 2001). The histological appearance of the fungus in corneal tissue is very similar to that seen in infection by species of *Aspergillus* or *Fusarium*, with septate branching hyphae and globular structures associated with the hyphae being noted. In fact, *Cylindrocarpon* spp. appear closely related both morphologically and taxonomically to *Fusarium* spp., with both sharing teleomorphs in the genus *Nectria* (Samuels and Brayford 1993; James et al. 1997). Because of morphological similarities, separation of the genus *Cylindrocarpon* from the genus *Fusarium* by cultural characteristics may become problematic at times (Guarro and Gené 1992). *Cylindrocarpon lichenicola* closely resembles *Fusarium solani*, but differs from it microscopically by forming macroconidia which are predominantly straight rather than curved, by having apical cells that are rounded rather than tapering, by having basal cells with truncate and offset rather than attenuated pedicels (foot cells) (Figure 4), by lacking microconidia, by having pigmented chlamydoconidia, and by the formation of a brown color rather than cream color on reverse of the Sabouraud glucose neopeptone agar (Iwen et al. 2000).

Dematiaceous fungi

The primary factor unifying the dematiaceous fungi is the dark pigmentation of the hyphae (McGinnis et al. 1986). This cell coloring results in colonies that are olive to black and in a brown-to-olive-to-black color in the cell walls of their vegetative cells, conidia or both. The dematiaceous fungi reported as causes of ocular infections, especially keratitis, include *Alternaria alternata*, *Aureobasidium pullulans*, *Bipolaris spicifera*, and *Bipolaris hawaiiensis*, *Curvularia lunata*, *Curvularia geniculata*, *Curvularia brachyspora*, *Curvularia senegalensis*, *Dichotomophthoropsis nymphaearum*, *Exophiala*

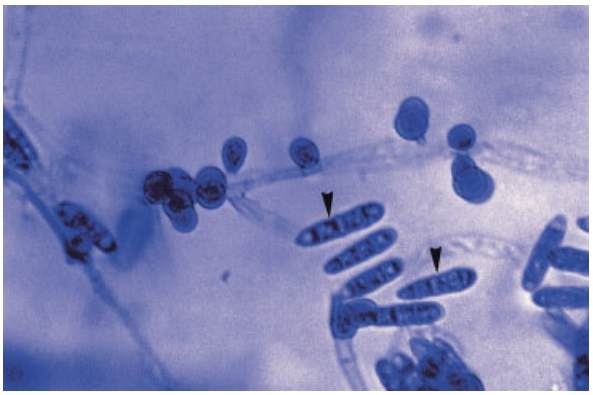

Figure 4 *Microscopic morphology of* Cylindrocarpon lichenicola *(7-day-old culture, Sabouraud glucose neopeptone agar). Multicelled macroconidia are predominantly straight, with rounded apical cells and truncate basal cells. Lactophenol cotton blue stain; magnification ×400*

jeanselmei var. *jeanselmei*, *Exophiala* (formerly *Wangiella*) *dermatitidis*, *Exserohilum rostratum*, *Exserohilum longirostratum*, *Lecytophora* (formerly *Phialophora*) *mutabilis*, *Lecytophora hoffmannii*, *Phaeoisaria clematidis*, *Phialophora verrucosa*, *Phoma oculo-hominis*, *Phoma* spp., and *Tetraploa aristata* (Newmark and Polack 1970; Jones and Christensen 1974; Forster et al. 1975b; Zapater et al. 1975; Punithalingam 1976; Liesegang and Forster 1980; Levenson et al. 1984; McGinnis et al. 1986; Douer et al. 1987; Wright et al. 1990; Ho et al. 1991; Stern and Buttross 1991; Marcus et al. 1992; Bouchon et al. 1994; Chang et al. 1994; Sutton et al. 1998; Guarro et al. 1999, 2000; Garg et al. 2000; Kaushik et al. 2001; Rishi and Font 2003). However, the validity of some of the earlier reports has been questioned (McGinnis 1980). In various studies, dematiaceous fungi are reported to be the third most important cause of fungal keratitis (behind *Aspergillus* and *Fusarium*) (Sundaram et al. 1989; Panda et al. 1997; Srinivasan et al. 1997; Garg et al. 2000; Gopinathan et al. 2002; Leck et al. 2002). Dematiaceous fungi may also cause infections of the orbit (Jay et al. 1988; Maskin et al. 1989), or intraocular infections (Kaushik et al. 2001). For diagnosis, direct microscopy of wet preparations of clinical material in 10 percent potassium hydroxide wet mounts permits the demonstration of the characteristic brown-pigmented septate fungal hyphae (Garg et al. 2000); lactophenol cotton blue stain can also be used (Figure 5) (Thomas et al. 1991b). Histology is also helpful in the diagnosis, although these fungi may be difficult to identify in hematoxylin and eosin-stained sections due to variability in the amount of pigment in the walls; to overcome this difficulty, the microscope condenser is lowered to make the hyphae more refractile, or the sections are stained by melanin-specific stains such as Fontana–Masson (Chandler 1991). Culture is required to confirm the etiologic diagnosis and to initiate appropriate treatment. Plates of Sabouraud glucose neopeptone agar or other appropriate media are inoculated with the material and incubated at 25–30°C for up to 3 weeks. In general, the colonies tend to be light-brown to olive-gray to black in color. The different genera and species are identified by the microscopic morphology of the conidia (McGinnis et al. 1986; Sutton et al. 1998).

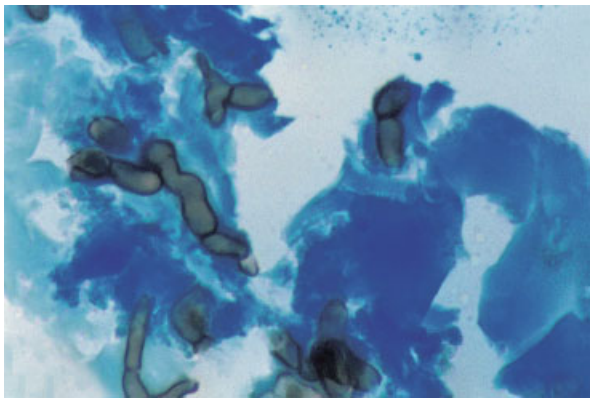

Figure 5 *Photomicrograph of pigmented fungal hyphae seen in the corneal scrape material of a patient with keratitis due to* Curvularia geniculata. *Lactophenol cotton blue stain; magnification ×400*

The form class Coelomycetes comprises asexual fungi that produce conidia within fruiting bodies named conidiomata. These structures may be spherical (pycnidia), with conidiogenous cells lining the inner cavity wall, or cup-shaped (acervuli), with the conidiogenous cells forming a palisade on the surface of the conidiomata. Coelomycetous fungi implicated in ocular infections include *Lasiodiplodia theobromae*, species of *Colletotrichum*, and *Phoma* spp.

Lasiodiplodia theobromae is an important cause of rot in corn, yams, citrus, bananas, and other plants, mainly in tropical regions (Adisa and Fajola 1983; Nwufo and Fajola 1988; Sutton et al. 1998). This fungus was initially implicated as an etiologic agent of human keratitis in two patients in India (Puttana 1967). Subsequently, reports from Colombia, France, Ghana, other parts of India, the Philippines, the southern USA, and Sri Lanka have confirmed the pathogenic potential of this fungus for the human cornea (Laverde et al. 1973; Valenton et al. 1975; Rebell and Forster 1976; Liesegang and Forster 1980; Slomovic et al. 1985; Thomas et al. 1991a, 1995; Gonawardena et al. 1994; Borderie et al. 1997; Garg et al. 2000; Gopinathan et al. 2002; Leck et al. 2002). This fungus causes severe keratitis in experimental animals and in humans (Puttana 1967; Rebell and Forster 1976; Thomas et al. 1991a, 1995; Borderie et al. 1997), perhaps due to its ability to secrete collagenases (Rebell and Forster 1976) and amylolytic and cellulolytic enzymes (Adisa and Fajola 1983; Nwufo and Fajola 1988). This fungus has been found to form intrahyphal hyphae and thickened cell walls in parasitized human corneal tissue (Figure 6a), and also in vitro, in the presence of an antifungal (Thomas et al. 1991a, 1995). Such intrahyphal hyphae have been demonstrated in experimental *Fusarium solani* keratitis in rabbits (Kiryu et al. 1991), and may represent a virulence factor for these fungi. In infected corneal tissues, *Lasiodiplodia theobromae* exhibits brown, highly bulged, septate hyphae. In culture on glucose peptone agar, the colony is rapidly growing (90 mm in one week), floccose, and gray to brown–black in color, the reverse being black (Figure 6b). Macroscopically visible fruiting bodies (pycnidia) are formed in culture. The pycnidial stromata, which are only formed on cornmeal or other nutritionally deficient media, are up to 5 mm in diameter, consisting of several pycnidia, each with a wide ostiole to permit release of the conidia; the conidia (Figure 6c) are 20–30 μm × 10–15 μm, initially colorless, ellipsoidal, and nonseptate, later becoming dark brown and septate, with longitudinal striations and

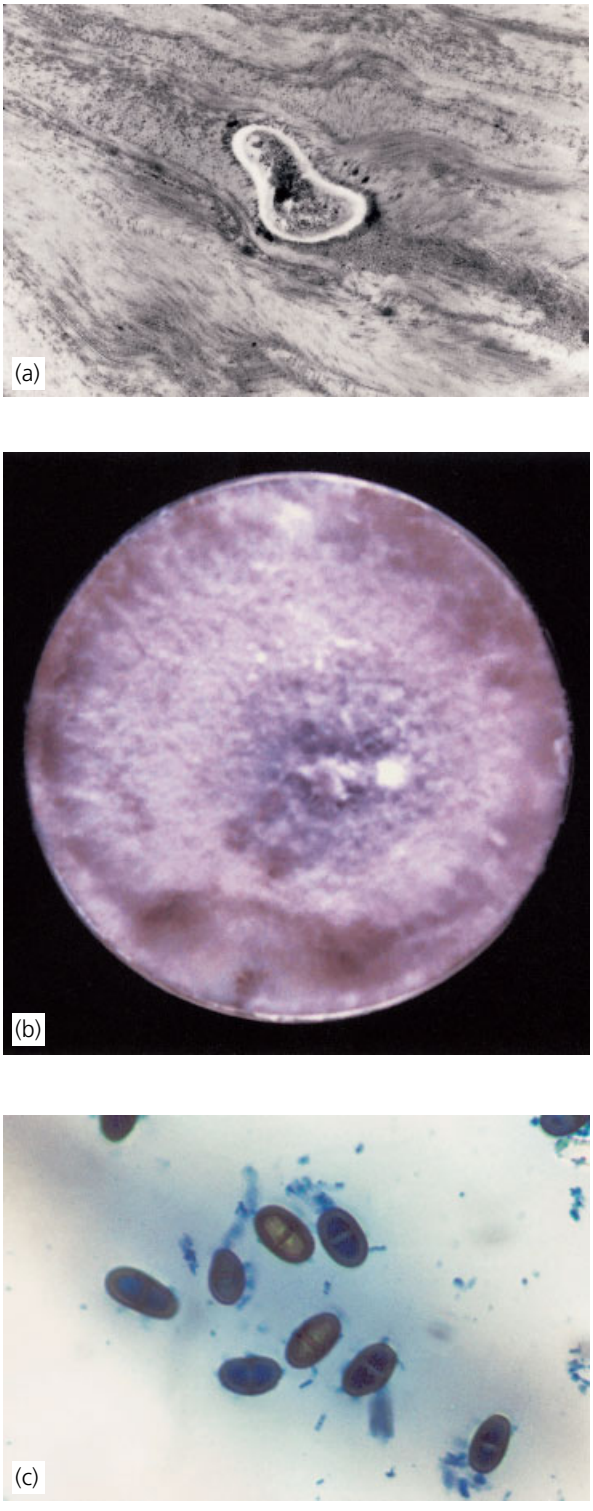

Figure 6 (a) *Electron micrograph of* Lasiodiplodia theobromae *fungal cell showing thickened cell wall in corneal scrape material (×6 050).* **(b)** *Macroscopic appearance of* Lasiodiplodia theobromae *(7-day-old growth) on Sabouraud glucose neopeptone agar.* **(c)** *Microscopic morphology of* Lasiodiplodia theobromae *(10-day-old culture, Sabouraud glucose neopeptone agar). Oval conidia, dark-brown, septate with longitudinal striations, truncate bases. Lactophenol cotton blue stain; magnification ×400*

truncate bases (Campbell et al. 1996). In vitro, *Lasiodiplodia theobromae* is resistant to many antifungals; minimal inhibitory concentrations exceeding 100 μg/ml for miconazole, ketoconazole, itraconazole, and natamycin, and ⩽10 μg/ml for econazole against ocular isolates of this fungus have been reported (Thomas et al. 1995).

The complex form genus *Colletotrichum* Corda comprises several hundred species, which are anamorphs of the genus *Glomerella* Spauld & H. Schrenk; they are placed in the order Phyllachorales, although there is evidence linking them to the Sordariales (Uecker 1994). *Colletotrichum* spp. are usually pathogenic on plants, in which they cause anthracnosis, necrosis, leaf spot, and fruit rot, and are believed to be only rarely pathogenic to humans. Although a search of the Medline database through PubMed yielded four reports describing 12 patients with *Colletotrichum* keratitis (Shukla et al. 1983; Ritterband et al. 1997; Yamamoto et al. 2001; Fernandez et al. 2002), a more detailed manual search through the results of various studies on mycotic keratitis reveals that species of *Colletotrichum* have been previously implicated as etiologic agents in as many as 20 patients with keratitis (Kaliamurthy et al. 2004). The species reported include *Colletotrichum gloeosporioides* in seven patients (Shukla et al. 1983; Matsuzaki et al. 1988; Yamamoto et al. 2001; Fernandez et al. 2002), *Colletotrichum coccodes* (reported as *Colletotrichum atramentarium*) in four (Liesegang and Forster 1980; Rosa et al. 1994), *Colletotrichum dematium* in three (Liao et al. 1983; Fernandez et al. 2002), *Colletotrichum graminicola* in one (Ritterband et al. 1997), *Colletotrichum capsici* in one (Upadhyay et al. 1991), and unidentified species of *Colletotrichum* in four (Fernandez et al. 2002). Antecedent ocular trauma appears to have been the principal risk factor for keratitis in most of these patients, but insulin-dependent diabetes mellitus, prolonged use of topical corticosteroids, and prior use of antivirals were also reported as risk factors. These patients received different antifungal drugs, principally topical natamycin alone (seven patients), amphotericin B alone or in combination with an azole or flucytosine (four patients), combined therapy with natamycin, intraocular amphotericin B, and oral azole (two patients), and natamycin followed by topical amphotericin B therapy. In most of the patients, the corneal lesions resolved completely with good visual recovery following initiation of medical therapy, possibly because the lesions were relatively superficial in nature. Microbiological investigations such as culture (Figure 7a) are essential to confirm the diagnosis of *Colletotrichum* keratitis and to ensure prompt initiation of specific antifungal therapy.

Colletotrichum dematium can be clearly distinguished from other species of *Colletotrichum* by the occurrence of falcate macroconidia (Figure 7b) (de Hoog and Guarro 1995). The gross appearance of these

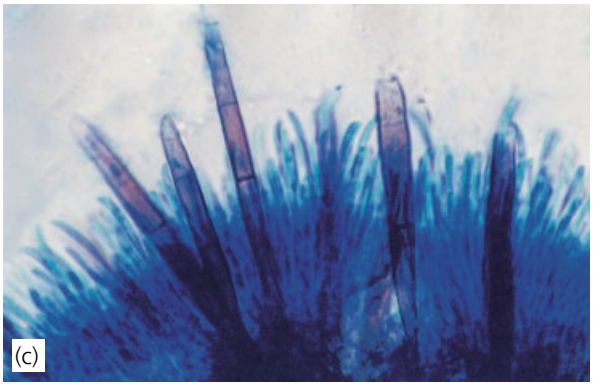

Figure 7 (a) *Macroscopic appearance of* Colletotrichum dematium *(7-day-old culture, Sabouraud glucose neopeptone agar).* **(b)** *Microscopic morphology of a* Colletotrichum *sp. (7-day-old culture, Sabouraud glucose neopeptone agar). Falcate macroconidia. Lactophenol cotton blue stain; magnification ×400.* **(c)** *Microscopic morphology of a* Colletotrichum *sp. (14-day-old culture, Sabouraud glucose-neopeptone agar). Brown-colored setae and sclerotia. Lactophenol cotton blue stain; magnification ×400*

macroconidia is very similar to that of the macroconidia of species of *Fusarium*. This may lead an inexperienced observer to mistakenly identify an isolate of *Colletotrichum dematium* as a *Fusarium* sp., particularly if the characteristic sclerotia and setae are not visible when the young culture is examined. To overcome this drawback, it is advisable to incubate all mycology culture plates for an additional 2 weeks after growth occurs, particularly if such falcate macroconidia have been observed (Kaliamurthy et al. 2004). It is important to remember that the macroconidia of *Colletotrichum dematium* are aseptate (*Fusarium* macroconidia are septate), and appear thinner than the macroconidia of species of *Fusarium*. Sclerotia and setae are found in abundance in older cultures of *Colletotrichum dematium* (Figure 7c); such structures are not observed in cultures of *Fusarium*.

Yeast and yeast-like fungi

Most yeast infections in corneal ulcers and other ocular infections are due to various *Candida* spp., predominantly *Candida albicans* and *Candida parapsilosis*. There is conclusive evidence to implicate species of *Candida* in dacryocystitis (Purgason et al. 1992), infectious crystalline keratopathy (Wilhelmus and Robinson 1991), intraocular lesions (Okhravi et al. 1998; Hidalgo et al. 2000; Jaeger et al. 2000), and keratitis (Rosa et al. 1994; Tanure et al. 2000); there is less convincing evidence for their implication in blepharitis, conjunctivitis, dacryocanaliculitis, and orbital lesions (McGinnis 1980; Behrens-Baumann 1999). The presence of small budding yeast cells (3–4 μm in size) and pseudohyphae in a corneal scraping is almost diagnostic for *Candida*. On microscopic examination of samples collected from the conjunctiva and lid margins, species of *Candida* can be easily distinguished from *Malassezia* spp. by the narrow attached base of the bud, the lack of symmetry of the yeast, and the off-axis position of the bud in *Candida*. Although both the yeast and the hyphal forms may be seen in corneal scrapings from *Candida* infections, the mycelial form is considered to be the invasive form (O'Day and Burd 1994). In culture, species of *Candida* form smooth, creamy-white colonies, resembling staphylococci in the very early stages of growth. The organisms grow well on blood agar, and do not require special conditions for isolation. It is important to identify isolates of *Candida* down to the species level, since different species exhibit varying susceptibilities to antifungal agents (Sutton et al. 1998). For example, 96–100 percent of isolates of *Candida parapsilosis* and 81–100 percent of isolates of *Candida albicans*, when tested by the recently standardized NCCLS broth microdilution method, were found susceptible to amphotericin B, flucytosine, fluconazole, itraconazole, ketoconazole, and miconazole; by contrast, only 59 and 77 percent of

isolates of *Candida tropicalis*, respectively, and 85 and 52 percent strains of *Candida glabrata*, respectively, were found to be susceptible to fluconazole and itraconazole (Sutton et al. 1998). However, the relevance of such in vitro susceptibility test results to the clinical outcome of ocular *Candida* infections remains unclear.

The yeast *Cryptococcus neoformans* var. *neoformans* is typically 5–10 μm in diameter (range 2–20 μm). Acute inflammation and necrosis may obscure the organism, but a useful cytological feature is the appearance of teardrop-shaped, narrow-based budding. The identification of this yeast as the etiologic agent in ocular infections still rests primarily on its cytomorphology (Klotz et al. 2000), with confirmation, as necessary, by special stains such as methenamine silver, which stain the organisms, and mucicarmine, periodic acid–Schiff, and alcian blue, which stain the capsule. These yeasts may be mistaken for *Histoplasma capsulatum* var. *capsulatum* when engulfed by histiocytes or when nonencapsulated (Powers 1998). There is clear evidence to show that *Cryptococcus neoformans* var. *neoformans* can cause blepharitis (Doorenbos-Bot et al. 1990; Coccia et al. 1999), chorioretinitis (Morinelli et al. 1993), endophthalmitis (Morinelli et al. 1993), keratitis (Liesegang and Forster 1980; Tanure et al. 2000), and solitary subretinal lesions (Hester et al. 1992). Recently, *Cryptococcus laurentii* was reported as the etiologic agent of keratitis, in conjunction with *Fusarium solani*, in one eye of a person wearing gas-permeable contact lenses (Ritterband et al. 1998). In vitro, 94–100 percent of strains have been found susceptible to fluconazole, itraconazole, amphotericin B, and ketoconazole (Sutton et al. 1998).

Zygomycetous fungi

Zygomycetes are filamentous fungi which exhibit aseptate or sparsely septate, hyaline hyphae. There are two orders, the Mucorales and the Entomophthorales, containing organisms causing human disease, although most human infections are caused by the Mucorales (Ribes et al. 2000). Ocular zygomycosis is commonly linked to *Rhizopus* spp., particularly *Rhizopus arrhizus*, but species of *Absidia*, *Apophysomyces*, *Cunninghamella*, *Mucor*, *Rhizomucor*, *Saksenaea*, and *Syncephalastrum* have also been implicated (Kaufman et al. 1988; Yohai et al. 1994; Marshall et al. 1997; Fairley et al. 2000; Ribes et al. 2000). Ocular infections caused by this group of fungi include rhino-orbital-cerebral zygomycosis (Anand et al. 1992; Yohai et al. 1994), where the spores are inhaled, and keratitis (Marshall et al. 1997), where the infection manifests after trauma. A *Rhizopus* sp. has also been reported as a cause of scleritis (Locher et al. 1998), but the evidence is not convincing. The detection of fungi belonging to the Mucorales in clinical material by direct microscopy is more significant than their isolation in culture since, even if cultured, contamination always has to be excluded (Richardson and Shankland 1999; Ribes et al. 2000). In clinical material, the hyphae are broad and aseptate or sparsely septate with right-angled (90°) branching (Figure 8); they do not possess parallel walls, nor do they radiate from a single point in tissues (Liu et al. 1998). Although the hyphae stain poorly with periodic acid–Schiff, they stain well with hematoxylin–eosin and Gomori methenamine silver stains. Cresyl-fast violet stains zygomycete walls brick red, and other fungi blue or purple (Richardson and Shankland 1999). In tissue sections, the hyphae are seen in the midst of associated prominent inflammation, necrosis, and invasion of blood vessels (Ribes et al. 2000). In vitro, 91 percent of strains of *R. arrhizus*, 100 percent of strains of *Absidia corymbifera*, and 50 percent of strains of *Apophysomyces elegans* were found susceptible to amphotericin B, while most strains were resistant to flucytosine, fluconazole, and itraconazole (Sutton et al. 1998). In practice also, amphotericin B is the drug of choice in the treatment of ocular zygomycosis.

Thermally dimorphic fungi

Blastomycosis, a granulomatous inflammatory disease caused by *Blastomyces dermatitidis*, usually occurs following inhalation of airborne spores that arise from the soil, and thus the primary infection is usually pulmonary; however, characteristic cutaneous lesions are often the presenting symptom. Eyelid lesions are believed to be the most common ocular manifestation of disseminated infection due to *Blastomyces dermatitidis* (Barr and Gamel 1986; Slack et al. 1992); however, a recent survey of 79 patients revealed just one with eyelid lesions (Bartley 1995). Other reported ocular lesions due to *Blastomyces dermatitidis* include conjunctivitis (Slack et al. 1992), orbital cellulitis (Vida and Moel 1974; Li et al. 1998), keratitis (Rodrigues and Laibson 1973),

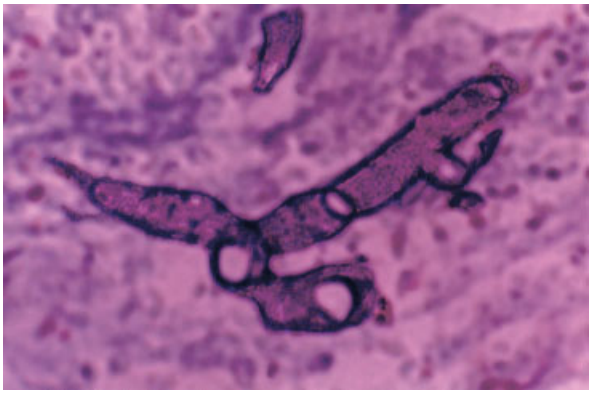

Figure 8 *Large, aseptate, irregular, bizzare hyphae of a zygomycetous fungus in tissue section of necrotic orbital material from a patient with rhino-orbital zygomycosis. Hematoxylin and eosin stain; magnification × 1 200*

and intraocular lesions such as anterior uveitis, iris nodules, or yellow-white posterior fundus lesions (Safneck et al. 1990), or endophthalmitis (Safneck et al. 1990; Li et al. 1998). Potassium hydroxide mounts of clinical material reveal characteristic yeasts with broad-based buds. The tissue reaction is a combination of suppurative and epithelioid cell granulomas with giant cells. Yeast-like spherical cells of *Blastomyces dermatitidis* are generally larger (8–20 μm) than those of cryptococci, and have refractile, double-contoured walls; broad-based budding is a useful criterion to differentiate *Blastomyces dermatitidis* from other dimorphic yeasts (Powers 1998). In culture at 26°C, the mycelial phase is noted (round or oval microconidia borne on conidiophores along sides of hyphae or terminally on hyphal branches), while at 37°C, on enriched media, the yeast phase is produced (large, oval, multinucleate yeasts, budding on a broad base, often in chains, with refractile cell walls). In vitro, most strains of *Blastomyces dermatitidis* are reported to be susceptible to amphotericin B, fluconazole, itraconazole, and ketoconazole (Sutton et al. 1998).

Coccidioidomycosis is caused by the thermally dimorphic fungal pathogen *Coccidioides immitis*. The occurrence of ocular lesions in coccidioidomycosis has been reported infrequently (Rodenbiker and Ganley 1980). Anterior segment manifestations are usually a mild hypersensitivity response, occurring as a chronic granulomatous iridocyclitis (Moorthy et al. 1994; Cunningham et al. 1998); however, phlyctenular conjunctivitis, episcleritis, scleritis, and keratoconjunctivitis may occur in association with underlying pulmonary infection, and lid granulomata and inflammation in disseminated disease. The manifestations in the posterior part of the eye range from asymptomatic focal chorioretinitis to a fulminating granulomatous process involving the entire eye. In potassium hydroxide mounts of pus or necrotic material from infected ocular tissue, large multinucleate thick-walled cells, the spherules, are seen, usually within giant cells (Rippon 1988); at maturity, these spherules are filled with spores, which escape by rupture of the cell wall. In vitro, more than 90 percent of strains of *Coccioides immitis* have been found susceptible to amphotericin B, miconazole, ketoconazole, and itraconazole, and 86 percent to fluconazole (Sutton et al. 1998).

The classical form of histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum* var. *capsulatum*, while a variant form, known as African or large-celled histoplasmosis, is caused by *Histoplasma capsulatum* var. *duboisii*. The mode of infection is presumably by inhalation or entry through broken skin surfaces, manifesting as acute pulmonary infections or cutaneous and subcutaneous disease; dissemination may occur in immunocompromised patients (Gonzales et al. 2000). *Histoplasma capsulatum* var. *capsulatum* has been isolated from the eyes of patients suffering from the 'presumed histoplasmosis syndrome,' suggesting that this fungus is the etiologic agent (Roth 1977; Khalil 1982). *Histoplasma capsulatum* var. *capsulatum* has been reported to cause endogenous endophthalmitis (Carroll and Franklin 1981; Goldstein and Buettner 1983; Gonzales et al. 2000), exogenous endophthalmitis after cataract extraction (Pulido et al. 1990), and panophthalmitis (Schwarz et al. 1977). Anterior segment lesions due to *Histoplasma capsulatum* var. *capsulatum* are less common but have been reported (Feman and Tilford 1985; Font et al. 1995). In patients with the acquired immunodeficiency syndrome (AIDS), *Histoplasma capsulatum* var. *capsulatum* has been reported to cause endophthalmitis (Gonzales et al. 2000) and lesions of the choroid, retina, and optic nerve (Specht et al. 1991; Yau et al. 1996). *Histoplasma capsulatum* var. *duboisii* has been reported to cause orbital lesions (Bansal et al. 1977; Ajayi et al. 1986). Organisms may be missed by direct microscopic examination of wet preparations of necrotic tissue, hence all material should be examined as stained smears (Powers 1998). Culture is done on media at 26°C (for mycelial phase) and enriched media at 37°C (for yeast phase). Conversion of the mycelial phase to the yeast phase must be demonstrated by culturing the mycelial phase on appropriate media at 37°C, or by inoculating the organism into a mouse, and reisolating it from the liver and spleen. In vitro, 100 percent of strains are susceptible to amphotericin B, itraconazole, and ketoconazole, 82 percent to fluconazole, and 50 percent to flucytosine (Sutton et al. 1998).

Paracoccidioides brasiliensis causes a severe, usually chronic disease involving the skin, lungs, and lymphoid organs. Ocular involvement usually represents reactivated disease, and commonly presents as a chronic papular or ulcerating lesion of the eyelid in a male over 30 years of age engaged in agriculture, and coming from a region endemic for paracoccidioidomycosis (Silva et al. 1988). Although ocular paracoccidioidomycosis, which is usually unilateral, rarely occurs in the absence of lesions in other parts of the body, palpebral lesions (Burnier and Sant'Anna 1997) and granulomatous uveitis (Dantas et al. 1990) have sometimes been reported as the first indications of the disseminated disease. In an experimental model of ocular paracoccidioidomycosis in guinea pigs obtained by the intracardiac inoculation of yeast forms of *Paracoccidioides brasiliensis*, ocular involvement was observed in 80 percent of the infected animals; the uvea, ciliary body, choroid, iris, lids, and the conjunctiva were the structures most commonly affected (Kamegasawa et al. 1988). In the initial stages, ocular paracoccidioidomycosis needs to be differentiated from hordeolum, bacterial blepharitis, trachoma, leishmaniasis, sporotrichosis, lupus erythematosus, tuberculosis, and secondary syphilis (Silva et al. 1988). Spherical yeast-like cells with multiple buds attached by narrow necks ('steering wheel forms') can be seen in 10 percent potassium hydroxide mounts of necrotic tissue material or in tissue sections. In culture, *Paracoccidioides*

brasiliensis exhibits dimorphism, which is temperature- and media-dependent.

Sporotrichosis, which is caused by the thermally dimorphic fungus *Sporothrix schenckii*, occurs worldwide in both tropical and temperate regions, and manifests as nodular lesions in the cutaneous and subcutaneous tissues that suppurate, ulcerate, and drain. Up to 1990, 17 episodes of endophthalmitis due to this fungus (Witherspoon et al. 1990) and orbital sporotrichosis (Streeten et al. 1974) had been reported. Since then, granulomatous uveitis progressing to scleral perforation and endophthalmitis due to use of corticosteroids (Cartwright et al. 1993), scleritis (Brunette and Stulting 1992), uveitis (Vieira-Dias et al. 1997), and a retinal granuloma associated with disseminated lesions (Curi et al. 2003) have been reported. In tissues or in culture at 37°C, the fungus appears as small, spherical, oval or elongated budding yeast cells with irregular-stained cytoplasm, or is 'cigar-shaped.' In culture at 26°C, the mycelial phase is recovered. In tissues, 'asteroid bodies' may occur, consisting of a central spherical or oval basophilic cell (3–5 μm diameter), surrounded by a thick, radiate, eosinophilic substance (which is believed to be a mass of antigen–antibody complexes); the asteroid body is characteristic of sporotrichosis only if the fungal cell within is typical of *Sporothrix schenckii*, since similar bodies may be observed in other mycoses (Rippon 1988).

Organisms of uncertain taxonomic classification

Rhinosporidiosis is caused by *Rhinosporidium seeberi*, an endosporulating microorganism traditionally considered to be a fungus but now of uncertain taxonomic classification (Pe'er et al. 1996). Rhinosporidiosis appears to be endemic in the Indian subcontinent (Chitravel et al. 1980; Krishnan et al. 1986; Moses et al. 1990; Shrestha et al. 1998); the prevalence of the condition in a south Indian village was reported to be 470/100 000 population (Chitravel et al. 1980). However, a significant number of cases has also been reported from other countries (Jimenez et al. 1984; Reidy et al. 1997). Farmers or their families, particularly children or young (up to 30 years of age) adults, and males, appear to be the most frequently affected; however, a female predominance is sometimes noted (Chitravel et al. 1980). The mode of transmission, while not definitely known, is believed to be by frequent exposure to water contaminated with spores of *Rhinosporidium seeberi* (Moses et al. 1990); in conjunctival rhinosporidiosis, the infection may arise by accidental injury to the eye by soil dust containing the spores (Jimenez et al. 1984). Lesions of rhinosporidiosis manifest as polypoid or papillomatous, very friable, proliferative outgrowths principally in the nasal cavity; ocular lesions may account for 13 percent of all lesions, the ratio of nasal to ocular lesions being 1.4:1 (Owor and Wamukota 1978). The principal ocular lesion in rhinosporidiosis is conjunctival, but involvement of the limbus, sclera, lacrimal sac (Krishnan et al. 1986; Kalavathy et al. 1998), and peripheral cornea (Bhomaj et al. 2001) have also been reported. Two distinct phases, namely, trophic and endosporulating, have been noted in the life cycle of this organism in tissues (Savino and Margo 1983), and the diagnosis of rhinosporidiosis is based on detecting these cyst-like structures in the affected tissues (Figure 9). The formation of the cyst wall appears to be a continuous morphological and biochemical spectrum throughout the cytological maturation of the organism (Sunba and al-Ali 1989); variations in this pattern have been noted to occur, probably as a protective mechanism, in concurrent rhinosporidiosis and *Papillomavirus* infection.

Pythium insidiosum, a cosmopolitan fungus-like aquatic organism, is found predominantly in swampy environments, where water lilies, various vegetables, and especially certain grasses support the asexual phase of its life cycle; motile zoospores, which appear to be chemotactically attracted to plant leaves or human/horse hairs, are the likely infective particles (Sutton et al. 1998). Originally considered to be an oomycetous member of the kingdom Fungi and later reclassified in the kingdom Protoctista (Imwidthaya 1994; Sutton et al. 1998), *Pythium insidiosum* is now considered to belong to the kingdom Stramenopila, organisms that are related to algae (Sutton et al. 1998). This organism causes diseases in plants and animals (horses, cattle, dogs, cats, or fishes), particularly in tropical and subtropical parts of the world (Imwidthaya 1994; Thianprasit et al. 1996). Virgile et al. (1993) presented what they believed to be the first case of a human corneal ulcer due to *Pythium insidiosum*. Subsequently, *Pythium insidiosum* has been reported as a cause of keratitis in Thailand (Imwidthaya 1994, 1995), where it has also been reported to cause subcutaneous lesions in thalassemic patients (Thianprasit

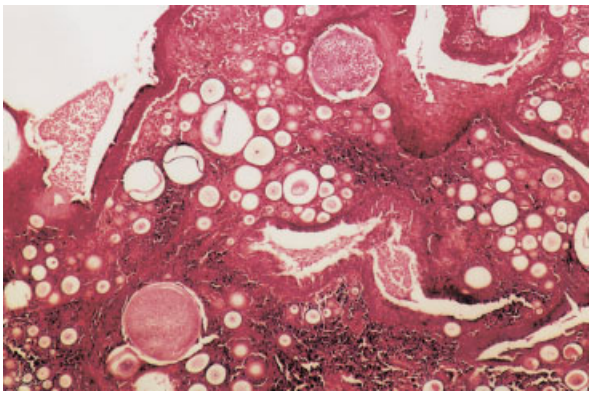

Figure 9 *Photomicrograph showing presence of sporangia (cysts) of* Rhinosporidium seeberi *in stroma of lacrimal sac. The cysts possess a sharply defined wall, with the largest sporangium revealing maturing endospores. Hematoxylin and eosin stain; magnification ×400*

et al. 1996), and in the temperate climate of New Zealand (Murdoch and Parr 1997), endophthalmitis (Srimuang et al. 1996), and orbital cellulitis with deep facial tissue involvement (Mendonza et al. 1996). Colonies on potato flakes agar at 25°C (optimal growth is at 33–36°C) are white to yellowish-white with short aerial hyphae; these are rapid-growing, and addition of human blood appears to stimulate colonial growth (Sutton et al. 1998). The most significant diagnostic microscopic morphological feature, biflagellate/motile asexual zoospores, may be induced by placing small pieces of *Pythium insidiosum* grown on agar into water and incubating at 37°C in the dark; after 1 hour incubation, encysted zoospores may be seen and after 24 hours, numerous zoosporangia may be observed (Sutton et al. 1998). In vitro susceptibility data are currently not available. Serological diagnosis of infection due to *Pythium insidiosum* by using sera from patients with keratoconjunctivitis or corneal ulcers with endophthalmitis has been reported (Srimuang et al. 1996). Badenoch et al. (2001) described a patient with keratitis in which DNA-based technology yielded a diagnosis of *Pythium insidiosum* keratitis.

Pneumocystis carinii was originally considered to be a protozoon, based on its morphology and response to antifungal drugs (Cailliez et al. 1996). However, subsequent to analysis of its nucleic acids, it has been reclassified as a member of the kingdom Fungi (Cailliez et al. 1996). It has been implicated as a cause of choroiditis (Dugel et al. 1990; Foster et al. 1991; Shami et al. 1991) and orbital infection (Friedberg et al. 1992) in patients with AIDS. In tissues, granulomatous inflammation mixed with foamy material containing *Pneumocystis carinii* is seen; round cysts with thickened walls, containing the crescent-shaped trophozoites, are demonstrated by the methenamine silver or Giemsa stains (Friedberg et al. 1992). No continuous in vitro culture system has been described for this organism. However, animals can be infected.

FUNGAL INFECTIONS OF THE ORBIT

Fungal infections of the orbit rarely occur spontaneously. Fungi usually gain access to the orbital space by direct extension from adjacent tissues (sinuses, teeth, lacrimal sac, lids); traumatic implantation of foreign bodies contaminated with fungi, or hematogenous seeding of fungi from a distant focus may also occur. Spread of infection from the sinuses to the orbit is believed to occur in 67–85 percent of orbital infections (Goodwin 1985; Parfrey 1986). In children, orbital complications usually accompany concurrent maxillary and ethmoid sinus infection, whereas in adults, frontal, maxillary, and ethmoidal sinus disease are about equally responsible for orbital complications (Hornblass et al. 1984). Due to the intimate relationship between the orbit and paranasal sinuses, virulent fungal pathogens causing sinusitis can devastate orbital structures by contiguous spread through the wafer-thin walls of the sinuses (Maskin et al. 1989). In fact, the variable presentations of orbital fungal infections parallel the presentations of paranasal sinus mycoses (Maskin et al. 1989; Klapper et al. 1997). Just as the distinctions between the different types of paranasal sinus mycoses are not clear because of closely associated patterns of clinical behaviour and pathological reactions (Levin et al. 1996; de Shazo et al. 1997), so also, the distinctions between the different types of orbital fungal infections, especially the chronic varieties, may not always be clear-cut.

Orbital fungal infections are usually demarcated into the invasive category, comprising the acute/fulminant (typified by rhinocerebral zygomycosis) and chronic/indolent (granulomatous) varieties (typified by orbital aspergillosis), and the noninvasive category, comprising the 'fungus ball' and orbital manifestations of allergic fungal rhinosinusitis (Klapper et al. 1997).

Since rhinocerebral zygomycosis and sino-orbital aspergillosis appear to be the principal types of orbital fungal infections, these are dealt with in greater detail.

Acute/fulminant orbital infections

RHINO-ORBITAL-CEREBRAL ZYGOMYCOSIS (RHINOCEREBRAL MUCORMYCOSIS)

Rhino-orbital-cerebral zygomycosis is the prototype of the acute/fulminant variety of invasive fungal orbital infection, usually running an acute course in an immunocompromised host (rarely in non-immunocompromised individuals), with angioinvasion and marked tissue necrosis being key features. The infection usually begins in the paranasal sinuses and then spreads to involve the orbit, face, palate, or brain (Anand et al. 1992). *Rhizopus* spp., especially *Rhizopus arrhizus*, are the most frequent causes (Ribes et al. 2000), less common causes being *Absidia corymbifera*, *Apophysomyces elegans* (Radner et al. 1995; Brown et al. 1998; Fairley et al. 2000), *Cunninghamella* spp. (Chetchotisakd et al. 1991), and *Saksenaea vasiformis* (Ajello et al. 1976; Kaufman et al. 1988). The major mode of disease transmission for the zygomycetes is presumed to be by inhalation of fungal conidia from environmental sources (Yohai et al. 1994; Ribes et al. 2000).

Being opportunistic pathogens, the Mucorales require a breakdown in immune defense mechanisms, especially those disease processes leading to neutropenia or neutrophil dysfunction, to cause disease. Neutrophil dysfunction induced by ketoacidosis underlies the majority of cases of human zygomycosis (Ribes et al. 2000), and this occurs even in juvenile diabetics. Although neutropenia induced by bone marrow suppression during chemotherapy, or immunosuppression induced following transplantation, is also believed to contribute to this type of pathology, zygomycosis was

observed in only 13 (0.9 percent) of 1 500 consecutive patients who underwent bone marrow transplantation (Morrison and McGlave 1993). Immune system compromise has also been linked to the development of zygomycosis. Corticosteroid use, in particular, may increase susceptibility to the development of zygomycosis by suppressing the normal inflammatory cell response, and also by inducing a diabetic state. An association has been noted between the occurrence of zygomycosis in patients on dialysis who were receiving deferoxamine/desferrioxamine for iron or aluminum overload (Daly et al. 1989; Boelaert et al. 1991; Slade and McNab 1991). Rhinocerebral manifestations were reported in 31 percent of 59 dialysis patients who developed zygomycosis due to *Rhizopus* spp. (Boelaert et al. 1991). In an alloxan-induced immunocompromised model of zygomycosis in mice, desferrioxamine iron chelation produced rhinocerebral zygomycosis in those animals that were challenged intrethmoidally with *Rhizopus* spores (Anand et al. 1992), presumably because desferrioxamine, in the iron-chelate form, feroxamine, provides iron to fungi belonging to the Mucorales. Rhino-orbital-cerebral zygomycosis may also supervene in the presence of predisposing factors such as protein-calorie malnutrition and iron overload, intravenous drug abuse, leukemia, aplastic anemia, myelodysplastic syndrome, concurrent diabetes mellitus, and adrenogenital syndrome, and treatment with the immunosuppressive medications necessary to maintain solid organ transplants, such as liver transplants, and in patients receiving donor leukocyte infusions (Boelaert et al. 1991; Weinberg et al. 1993; Nussbaum and Hall 1994; Penalver et al. 1998; Raj et al. 1998; Webb et al. 1998; Stern and Kagan 1999; Ribes et al. 2000). The disease may rarely occur in non-immunocompromised individuals if there is some associated antibiotic use or a breakdown in the mucocutaneous barrier (Bhattacharya et al. 1992; Parthiban et al. 1998; Saltoglu et al. 1998); such patients may respond to treatment better than immunocompromised patients.

In recent years, *Apophysomyces elegans* has been reported as a cause of rhino-orbital-cerebral zygomycosis in immunocompetent hosts (Radner et al. 1995; Brown et al. 1998; Fairley et al. 2000). The disease entity caused by *Apophysomyces elegans* appears to differ from that caused by the more common genera of zygomycetes in that the disease frequently follows traumatic inoculation and/or soil contamination, and tends to occur in warm climates in patients who do not exhibit well-recognized immunological or metabolic abnormalities (the patients are frequently immunocompetent) (Fairley et al. 2000).

Fever has been reported to occur in 44 percent of patients with rhinocerebral zygomycosis, nasal ulceration, or actual necrosis in 38 percent and periorbital or facial edema in 34 percent; other findings (in descending order of frequency of occurrence) include decreased vision, ophthalmoplegia, sinusitis, headache, facial pain, decreased mental status, leukocytosis, nasal discharge, nasal stuffiness, corneal anesthesia, orbital cellulitis, and proptosis (Yohai et al. 1994). Necrosis of the facial skin and bone with typical black eschar formation, which is usually considered to be pathognomonic of rhinocerebral zygomycosis, is reported by some to be a late manifestation (Ferry and Abedi 1983). Others believe that the classic presentation in a susceptible patient is with unilateral severe headache and facial pain, nasal stuffiness with granular or purulent discharge, facial or eyelid edema, fever, and leukocytosis (Nussbaum and Hall 1994). Bacterial cavernous sinus thrombosis may sometimes mimic rhino-orbital-cerebral zygomycosis, but early visual loss and retinal artery occlusion are believed to suggest a diagnosis of the latter condition, since blindness is a much later finding in the former condition (Fairley et al. 2000).

Orbital findings result from ischemic necrosis of the intraorbital contents and cranial nerves; however, bony involvement is uncommon because of the angioinvasive nature of the fungus. Fungal invasion of the eyeball in patients with rhino-orbital-cerebral zygomycosis is considered to be a poor prognostic index, since all six patients reported up to 1992 with this condition succumbed to the disease (Sponsler et al. 1992). Rhino-orbital-cerebral zygomycosis has also been reported to manifest as a painless orbital apex syndrome without any sign of orbital cellulitis or acute systemic disease (Balch et al. 1997), which may have a good outcome with medical therapy, orbital infarction syndrome (Borruat et al. 1993), bilateral cavernous sinus thrombosis (Van Johnson et al. 1988; Alleyne et al. 1999), isolated pontine infarction (Calli et al. 1999), palatal ulcer (Van der Westhuijzen et al. 1989), chiasmal infarction and sudden blindness (Lee et al. 1996), fever with right-sided hemiparesis, and dysarthria in juvenile diabetics (Adler et al. 1998) and numbness, loss of sensation over the temporal region, loss of vision, and proptosis (Attapattu 1995).

Magnetic resonance imaging (MRI) and computerized tomography (CT) are important aids in establishing an anatomic diagnosis in suspected rhinocerebral fungal infections (Moll et al. 1994; Levin et al. 1996). Reported MRI manifestations of rhino-orbital-cerebral zygomycosis include (Press et al. 1988): sinus and orbital disease followed by deep facial extension, involvement of the basal portions of the cerebral hemispheres, brainstem, and hypothalamus and hyperintense regions (signifying intracerebral inflammation). Limitations in establishing the diagnosis of both cerebral zygomycosis and cavernous sinus thrombosis (Van Johnson et al. 1988) may be overcome by performing sequential CT and MRI studies in a patient suspected of having rhino-orbital-cerebral zygomycosis (Boelaert 1994; Moll et al. 1994). It is also not clear whether there are any specific radiological findings for rhinocerebral zygomycosis. CT nonenhancement of the superior ophthalmic artery and vein may

represent a specific sign of orbital zygomycosis (Kilpatrick et al. 1984; Gamba et al. 1986). McLean et al. (1996) documented, by MRI and pathology, the perineural spread of rhinocerebral zygomycosis, following the trigeminal nerve to the pons. While CT and MRI scans help to define the extent of bone and soft-tissue destruction, they are probably more useful in planning surgical intervention than in establishing a diagnosis. MRI scanning may be preferred for the diabetic patient in whom CT contrast agents may be contraindicated.

A prompt and accurate diagnosis of orbital zygomycosis necessitates a high level of clinical suspicion, and good coordination between the clinical and laboratory staff. Multiple biopsies should be taken from necrotic tissue and, if possible, from the nose, paranasal sinuses, and oropharynx as well; abscesses should be aspirated, and lesions on the mucous membranes should be irrigated or scraped (Richardson and Shankland 1999). Swabs are not satisfactory. Once collected, samples should be transported at once to the laboratory since immediate information is required and because zygomycetes are rather fragile organisms that do not survive more than a few hours at refrigerator temperature; if overnight storage is required, samples may be kept in Stuart's transport medium and left at room temperature. The tissue should be minced and not ground, to ensure that any viable fungal elements are not destroyed. Zygomycetes may not be found at the center of the necrotic tissue but, rather, at the edge or proximal to the necrotic material (Richardson and Shankland 1999).

The microscopic demonstration of zygomycetes in clinical material taken from necrotic lesions is more significant than their isolation in culture (Figure 10a), since zygomycetous fungi are frequent contaminants in the clinical microbiology laboratory (Ribes et al. 2000). In tissue material stained by hematoxylin-eosin, abundant, large, often bizzare, aseptate or sparsely septate, irregularly branching hyphal elements (Figure 8) can be seen invading intact tissue; however, failure to observe such elements does not exclude the diagnosis of such an infection. Although nasal, palatal, and sputum cultures seldom contribute to the diagnosis, isolation of Mucorales from sputum, aspirated material from sinuses, or bronchial washings taken from diabetic or immunosuppressed patients should not be ignored (Richardson and Shankland 1999). The confirmatory identification of the genus or species requires culture of the specimen. Although zygomycetes are not especially fastidious, cultures of necrotic tissue frequently fail to yield fungi even when direct microscopy is positive; therefore, culture media should be heavily inoculated with as much material as possible. Sabouraud glucose neopeptone agar (with an antibacterial such as chloramphenicol or polymyxin B, but no cycloheximide) is adequate; squares of sterile home-made bread (without preservatives) have also been suggested. Mucorales usually grow within 2–5 days (Figure 10a), and rapidly fill the petri plate or tube.

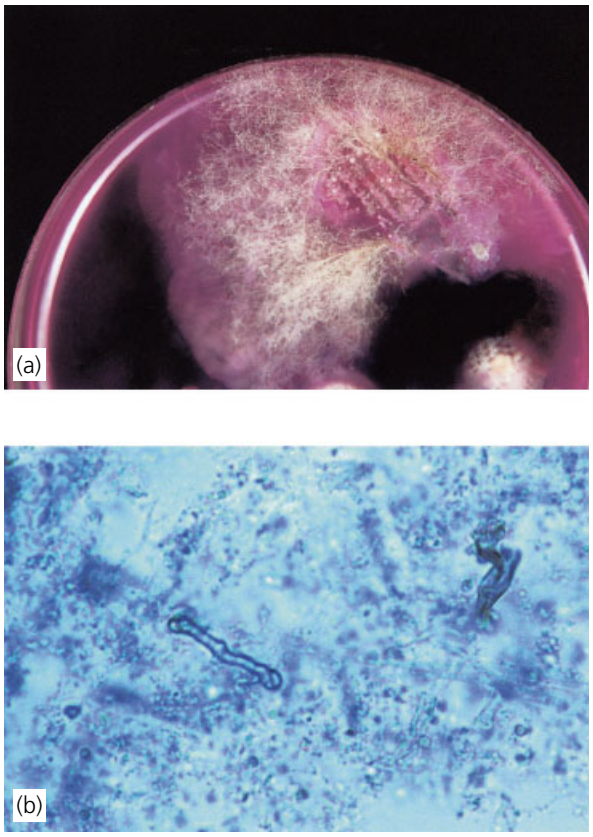

Figure 10 (a) *Macroscopic appearance of a* Mucor *sp. (isolated from rhino-orbital zygomycosis) on rose bengal agar.* **(b)** *Photomicrograph of nasal material from a patient with allergic fungal rhinosinusitis, exhibiting sparse fungal hyphae (*Aspergillus fumigatus *recovered in culture). Lactophenol cotton blue stain; magnification ×400*

In addition to the conventional methods of diagnosis, Kaufman et al. (1988) were able to demonstrate antibodies to *Saksenaea vasiformis* by enzyme-linked immunosorbent assay in a patient with rhinocerebral zygomycosis due to this fungus. However, demonstration of antibodies to Mucorales by this serological technique may not be possible if the disease progresses so rapidly that the patient is dead before specific antibodies can be formed.

General principles in the treatment of acute invasive rhinocerebral zygomycosis and other acute invasive orbital mycoses include:

- control of diabetic ketoacidosis or other systemic underlying diseases, and elimination of predisposing factors
- surgical debridement and restoration of sinus drainage
- intravenous amphotericin B (conventional or lipid associated).

In the diabetic patient, there should be prompt correction of acidosis and other metabolic abnormalities, and elimination of predisposing factors.

Surgery consists of wide local excision and debridement of all involved and devitalized oral, nasal, sinus, and orbital tissue while establishing adequate sinus and orbital drainage (Kohn and Hepler 1985); this may be quite mutilating and multiple operations are often required. Infected tissue typically bleeds little due to the vaso-occlusion caused by the Mucorales; therefore, necrotic tissue can be removed until normal bleeding is encountered. However, this may not be possible with extensive infections which extend to the dura or beyond (Yohai et al. 1994). Since rhinocerebral zygomycosis spreads by direct contiguous extension to surrounding tissues, and because the zygomycete hyphae are easily recognized on frozen section biopsies, this disease entity is potentially amenable to complete resection by frozen section guidance; one such technique of frozen section-guided surgical debridement for biopsy-proven rhino-orbital-cerebral zygomycosis, in conjunction with local and systemic amphotericin B, has recently been described (Langford et al. 1997). Serial radiological imaging may also help to identify the extent of disease and response to treatment. In recent years, endoscopic sinus surgery has been tried, alone or in combination with the traditional surgical procedures, to attain the goal of radical resection with less operative morbidity and greater operative accuracy (Jiang and Hsu 1999).

The interval between onset of symptoms and surgery was found to play a key role in the ultimate survival of evaluable patients with rhino-orbital-cerebral zygomycosis reported in the literature between 1970 and 1994; when the interval was 1–6 days, as many as 81 percent survived compared to 42 percent when the interval was 13–30 days (Yohai et al. 1994). In extreme cases, for example in an acutely infected orbit with a blind immobile eye, orbital exenteration, which entails removal of the eyeball together with its extraocular muscles and other soft tissues of the orbit, has to be performed.

Although treatment modalities have not undergone clinical trials, and in spite of the emergence of new antifungals in the therapy of invasive fungal disease, the combination of aggressive surgical debridement and intravenous amphotericin B therapy continues to be the treatment of choice in rhino-orbital-cerebral zygomycosis (O'Keefe et al. 1986; Yohai et al. 1994). An analysis of the case records of 145 patients with rhino-orbital-cerebral zygomycosis reported between 1970 and 1994 revealed that when the interval from onset of symptoms to initiation of amphotericin B therapy was 6 days or less, 76 percent of patients survived, but when the interval was 7–30 days, only 36 percent survived (Yohai et al. 1994). Amphotericin B has been administered by various routes in an effort to improve the outcome of this condition, which normally results in extreme morbidity. Kohn and Hepler (1985) were among the first to use this approach by supplementing the standard therapeutic regimen for rhino-cerebral zygomycosis with daily amphotericin B (1 mg/ml) irrigation and packing of the involved orbit and sinuses; this is likely to have aided the delivery of amphotericin B to poorly perfused infected and/or necrotic tissue, so that excellent results were obtained in their small series of patients, even though orbital exenteration was not performed. The use of a nasal-sinus catheter (Cohen and Greenberg 1980) or percutaneous catheter (Nussbaum and Hall 1994) for local irrigation, the use of adjunctive local nebulized amphotericin B (Raj et al. 1998) as well as administration of amphotericin B by using the intracavitary/interstitial and cerebrospinal fluid (intraventricular) routes (Adler et al. 1998), in addition to conventional intravenous administration of amphotericin B, have also been tried.

Since the use of intravenous amphotericin B is fraught with numerous side effects, attempts have been made in recent years to prepare new formulations of amphotericin B which maintain the efficacy of the antifungal without its toxicity. One such formulation is amphotericin B encapsulated in liposomes (liposomal amphotericin B). Lipid association significantly decreases the toxicity of amphotericin B, enabling higher dosages to be administered, and appears to enhance delivery to fungi, infected organs, and phagocytes. Treatment comprising liposomal amphotericin B and surgical debridement has been reported useful for a small number of patients with rhinocerebral zygomycosis (Penalver et al. 1998; Saltoglu et al. 1998). Strasser et al. (1996) documented the medical cure of a 60-year-old diabetic woman with rhinocerebral zygomycosis involving the cavernous sinus whose infection responded to medical therapy with another modification of this drug, namely, amphotericin B lipid complex. Yet another modification is amphotericin B colloidal dispersion, a 1:1 complex of cholesteryl sulfate and amphotericin B; administration of this preparation, in combination with surgical debridement, resulted in cure of life-threatening rhinocerebral zygomycosis in two patients, and in a cure of the fungal infection in a third patient (Moses et al. 1998).

Additional therapeutic modalities, including the triazoles itraconazole and fluconazole, have been reported useful in therapy of a small number of patients with rhinocerebral zygomycosis (Sica et al. 1993; Parthiban et al. 1998); however, further clinical studies are necessary to substantiate these preliminary results. The efficacy of granulocyte colony-stimulating factor, in conjunction with fluconazole therapy, was evaluated in the treatment of four patients with histopathologically proven rhinocerebral zygomycosis (Sahin et al. 1996); two patients refractory to fluconazole therapy were treated with liposomal amphotericin B. The improvement in clinical manifestations was closely related to neutrophil recovery, and all patients were alive at the end of therapy; in addition to surgical debridement and antifungal therapy, granulocyte colony-stimulating factor seems to have played a role in their survival. Hyperbaric oxygen has also been described as an addi-

tional therapeutic option. Yohai et al. (1994) evaluated the effect of hyperbaric oxygen therapy in patients with a low survival rate, that is, in those with bilateral rhinocerebral zygomycosis; 22 percent of patients who received standard therapy survived while 83 percent of patients who received standard therapy plus adjunctive hyperbaric oxygen survived. Although the possible adverse effects of hyperbaric oxygen therapy, such as decompression sickness and aeroembolism, need to be kept in mind (Maskin et al. 1989), it has been suggested that hyperbaric oxygen be considered as part of the initial therapy and should be persisted with until evidence of disease regression is observed (Yohai et al. 1994).

In a review of the published case histories of 145 patients who presented with rhinocerebral zygomycosis from 1970 to 1994, delayed diagnosis and treatment, hemiparesis or hemiplegia, bilateral sinus involvement, leukemia, renal disease, and treatment with desferrioxamine were identified as significant factors related to a lower survival rate; the association of facial necrosis with a poor prognosis also appeared to be clinically important (Yohai et al. 1994). The presence of ocular infiltration by fungus may indicate a poor prognosis in rhinocerebral zygomycosis (Sponsler et al. 1992). The mortality of rhinocerebral zygomycosis caused specifically by *Apophysomyces elegans* is currently unknown because of the rarity of diagnosed cases, but it would seem to fall at the more favorable end of the spectrum (Fairley et al. 2000).

ACUTE ORBITAL INFECTIONS DUE TO OTHER FUNGI

Fungi belonging to the order Mucorales are so frequently the causes of acute orbital mycoses that the term 'mucormycosis' has often been used as being synonymous with a fulminant orbital fungal infection. However, species of *Aspergillus* (Levin et al. 1996), *Scedosporium apiospermum* (*Pseudallescheria boydii*) (Anderson et al. 1984), and different genera of dematiaceous filamentous fungi (Jay et al. 1988; Maskin et al. 1989) may also cause this disease entity.

Although orbital aspergillosis usually manifests as a chronic condition, it may sometimes present as acute fulminant disease, where rapid, uncontrollable progression leads to intracranial involvement and sometimes death (Mauriello et al. 1995; Kronish et al. 1996; Johnson et al. 1999; Kusaka et al. 2003); in such cases, the key presenting complaints include abrupt onset of proptosis, ophthalmoplegia, blepharoptosis with precipitous visual loss, debilitating periorbital pain or headache, without inflammatory signs, and sometimes a temporal arteritis (Mauriello et al. 1995; Kronish et al. 1996; Hutnik et al. 1997; Johnson et al. 1999). Acute orbital infections caused by *Scedosporium apiospermum* and dematiaceous fungi are clinically characterized by rapid acute onset, orbital pain, fever, rhinorrhea, and signs of orbital inflammation, such as acute visual loss and total internal and external ophthalmoplegia.

In the treatment of fulminant rhino-orbital infections caused by fungi other than the Mucorales, treatment is essentially as described for orbital zygomycosis; however, antifungals other than amphotericin B may play a prominent role. The dematiaceous fungus *Bipolaris hawaiiensis* was identified as the cause of a devastating bilateral optic neuropathy and orbitopathy following contiguous fungal sinusitis in an apparently immunocompetent young man. Therapy with 3 700 mg of amphotericin B failed, but itraconazole therapy was initiated because of in vitro susceptibility of the fungus to itraconazole, and the detection of fungicidal levels of itraconazole in the sinus mucosa after oral therapy; at the time of reporting, the patient had been on itraconazole for 16 months and appeared stable (Maskin et al. 1989). An acute orbital infection and brain abscess due to *Scedosporium apiospermum* (*Pseudallescheria boydii*) in a 4-year-old boy failed to respond to 6 days of intravenous amphotericin B but was successfully treated with intravenous miconazole and multiple surgical debridements (Anderson et al. 1984). Surgical debridement of the orbit and a 6-week course of intravenous miconazole resulted in reduction of *Scedosporium apiospermum* orbital infection in another patient as well (Nunery et al. 1985).

Chronic invasive orbital infections

The chronic invasive form of fungal sinusitis, which slowly results in rhino-orbital-cerebral disease, manifests as a slowly destructive disease process. It may occur in immunocompromised (Levin et al. 1996) or non-immunocompromised patients (Klapper et al. 1997).

CHRONIC ORBITAL ASPERGILLOSIS

It is not clear whether the entity commonly referred to as 'chronic orbital aspergillosis,' which is described as being more common in hot, humid climates (Deans et al. 1996; Krause and Bullock 1996), refers to the chronic invasive disease (associated with granulomatous inflammation and fibrosis) occurring in immunocompromised persons (Levin et al. 1996), or to chronic invasive disease that occurs in non-immunocompromised patients (Klapper et al. 1997). *Aspergillus* spp. have been implicated in a wide variety of primary ocular orbital conditions. Predisposing factors include alcoholism, high-dose corticosteroid therapy, insulin-dependent diabetes mellitus and AIDS (Mauriello et al. 1995; Kronish et al. 1996; Johnson et al. 1999). Chronic presentations of orbital aspergillosis, which are more common than the acute variety, tend to be more localized and include an aspergilloma extending from one of the periorbital sinuses into the orbit, an aspergilloma in an exenteration socket, a complex dacryocystitis, a nerve tumor, and

postoperative periorbital swelling (Swoboda and Ullrich 1992; Levin et al. 1996). The presenting complaints in chronic disease may be nonspecific. Chronic sino-orbital aspergillosis may present subacutely in older patients with diabetes mellitus or pulmonary diseases, and in those receiving immunosuppressive drugs. Some presentations of orbital aspergillosis, such as optic nerve involvement, may lead to the use of systemic corticosteroids, delaying diagnosis and, possibly, potentiating the infectious process. In neutropenic, or otherwise immunocompromised patients, a high index of suspicion should be maintained to forestall the emergence of fulminant aspergillosis (Levin et al. 1996). For diagnosis of orbital aspergilloma, aspiration cytology and immunohistochemistry have been described (Oneson et al. 1988).

Management of invasive sino-orbital aspergillosis, as has been reported in patients with AIDS (Vitale et al. 1992; Meyer et al. 1994; Kronish et al. 1996; Johnson et al. 1999), revolves around aggressive surgical debridement and the use of intravenous amphotericin B. In spite of these measures, the prognosis is very poor, and mortality may be as high as 75–80 percent (Kronish et al. 1996; Johnson et al. 1999), primarily due to intracranial extension of the disease process. Most patients succumb to their illness within a few months. However, the survival of a patient with invasive aspergillosis involving the orbit, paranasal sinus, and central nervous system for more than 9 years has recently been reported (Kusaka et al. 2003). The prognosis of this disease depends on the location and duration of the infection and the patient's immunological status, with sphenoidal aspergillosis being particularly aggressive in nature due to its close relation to the skull base. The use of protease inhibitors may prolong survival in some of these patients (Johnson et al. 1999). Fortunately, therapy of the more localized forms of orbital aspergillosis carries a better prognosis. In such cases, conservative orbital debridement (for example, resection of an orbital abscess) with amphotericin B administered intravenously and locally (by means of an indwelling cathether or intraorbital injection), may be effective, especially in patients with reversible immunosuppression and good preoperative visual acuities (Harris and Will 1989; Cahill et al. 1994; Seiff et al. 1999). Rieske et al. (1998) described the use of amphotericin B colloidal dispersion in a child who had sino-orbital aspergillosis. Massry et al. (1996) reported successful resolution of sino-orbital aspergillosis following initiation of itraconazole treatment, without recurrence at 10 months follow-up, in an immunocompetent patient in whom traditional therapeutic modalities (surgical debridement and amphotericin B therapy) had not resulted in resolution; thus, oral itraconazole could be considered as a treatment option in orbital aspergillosis occurring in immunocompetent patients who have recurrent or recalcitrant disease, or in those who cannot tolerate amphotericin B.

CHRONIC RHINOCEREBRAL ZYGOMYCOSIS

In the chronic presentation of rhinocerebral zygomycosis, which is less common than the acute form, the disease is indolent and slowly progressive over weeks to months. Harril et al. (1996), who described two patients with chronic rhinocerebral zygomycosis treated at their institution and reviewed 16 other cases reported in the English-language literature, observed that the median time from onset of symptoms to diagnosis was 7 months; the most common presenting features of chronic rhinocerebral zygomycosis were ophthalmological and included ptosis, proptosis, visual loss, and ophthalmoplegia. This entity was found to occur predominantly in patients with diabetes and ketoacidosis. The incidence of internal carotid artery and cavernous sinus thrombosis was higher in patients with chronic rhinocerebral zygomycosis than in those with the acute disease, although the overall survival rate for the former was 83 percent.

CHRONIC ORBITAL INFECTIONS DUE TO OTHER FUNGI

Other fungi implicated as causes of chronic invasive orbital infection include *Paecilomyces lilacinus*, *Scedosporium apiospermum*, *Bipolaris spicifera*, and *Bipolaris hawaiiensis*, other genera and species of hyaline and dematiaceous fungi, and dimorphic fungi, such as *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* var. *duboisii* (Olurin et al. 1969; Streeten et al. 1974; Vida and Moel 1974; Agrawal et al. 1979; Nunery et al. 1985; Jay et al. 1988; Maskin et al. 1989; McGuire et al. 1991; Jacobson et al. 1992). The patients may present with nasal congestion, postnasal drip, and chronic sinus pain, citing frequent bouts of acute sinusitis (Washburn et al. 1988). There may be slowly progressive unilateral proptosis with decreased vision. In *Bipolaris* infections, impairment of extraocular motility and proptosis appear to occur more frequently than visual loss (Jacobson et al. 1992). A mass may be seen originating from an adjacent paranasal sinus, with sclerotic margins, and producing an inflammatory reaction in the orbit (Washburn et al. 1988). Other orbital inflammatory signs may be absent. Histologically, this form is characterized by granulomatous inflammation and tissue invasion. Although the prognosis in this variety of disease is certainly much better than that in acute fulminant disease, intraorbital and intracranial extension may occur, leading to significant morbidity (Klapper et al. 1997). Treatment is surgical debridement and systemic antifungal therapy; antifungals other than amphotericin B may play an important role in such infections.

Chronic localized noninvasive fungal infections

Chronic, localized noninvasive fungal infections or 'fungus balls' tend to occur in normal anatomic cavities

(e.g. paranasal sinuses) or cavitations induced by disease (pulmonary cavities due to tuberculosis). An example of such 'fungus balls' is the aspergilloma, which may occur in a paranasal sinus or in a lung cavity (Klapper et al. 1997; Latgé 1999). Histologically, it manifests as a non-invasive, tightly packed fungal mycelium or 'fungus ball' (mycetoma) (Latgé 1999). The normal orbital cavity is filled with the eyeball and ocular adnexa, and surrounding orbital fat. Hence, a fungus ball can occur only where orbital exenteration (removal of the entire contents of the orbit) has been performed. Levin et al. (1996) described the occurrence of *Aspergillus* infection in an exenterated socket. This type of 'fungus ball' may also occur in the orbital prosthesis used to fill an exenterated socket. Oestreicher et al. (1999) described the occurrence of a fungal abscess (subsequently shown by histopathology to be filled with fungal hyphae having the morphology of *Aspergillus* spp.) within an hydroxyapatite orbital implant 58 months after uncomplicated implant surgery; the patient's symptoms resolved following removal of the implant.

Allergic fungal rhinosinusitis with orbital involvement

The name 'allergic *Aspergillus* sinusitis' was proposed in 1983 (Katzenstein et al. 1983) to describe a newly recognized form of chronic sinusitis, but this entity is now called 'allergic fungal sinusitis' or 'allergic fungal rhinosinusitis' since many genera of dematiaceous fungi (*Bipolaris*, *Exserohilum*, *Curvularia*, and *Alternaria*) are now believed to be responsible for many cases (Adam et al. 1986; Brummund et al. 1986; Klapper et al. 1997; Ferguson 1998). This condition occurs in immunocompetent, atopic individuals. Here, the fungus does not invade the surrounding tissue, but serves as an 'allergen,' resulting in the formation of a thick ('peanut butter-like') tenacious, green or brown 'allergic' mucin. The patients may give a history of nasal polyposis or recurrent chronic sinusitis. Symptoms described include nasal obstruction, local pain, rhinorrhea, visual loss, diplopia, proptosis, epiphora, cranial nerve palsies, and facial deformity. Up to 17 percent of patients with allergic fungal rhinosinusitis may experience orbital symptoms (Klapper et al. 1997). Allergic fungal rhinosinusitis is a unique subset of fungal sino-orbital disease which differs from invasive sino-orbital disease in many respects. Key elements to the diagnosis of this condition include a predominantly eosinophilic response of the sinus mucosa, the presence of the characteristic mucoid exudate containing fungal hyphae (Figure 10b), peripheral blood eosinophilia, serum precipitins against the fungus involved, elevated serum total and fungus-specific IgE and IgG concentrations, and an immediate hypersensitivity response to the concerned fungal antigen (Brummund et al. 1986). Patients with allergic fungal rhinosinusitis generally have high levels of total IgE and IgE-mediated atopy to multiple fungal and nonfungal antigens; hence, immunotherapy has now been advised for such patients since it appears to significantly alter the clinical course of these patients, sparing them from repeated surgery and the use of systemic corticosteroids (Mabry and Mabry 1998). It has been advised that patients with allergic fungal rhinosinusitis should receive:

- conservative yet thorough surgical exenteration of the lesion by endoscopic techniques
- adjuvant therapy using perioperative systemic corticosteroids and topical corticosteroids as the patients heal and before beginning immunotherapy
- irrigation and debridement as necessary after surgery
- immunotherapy with all relevant fungal and nonfungal antigens to which they are found to be allergic about a month or so following surgery (Ferguson 1998; Mabry and Mabry 1998).

Allergic fungal rhinosinusitis does not require aggressive surgical debridement or intravenous amphotericin B.

MYCOTIC INFECTIONS OF EYELIDS

Although infections of the eyelids are caused most frequently by bacteria (particularly *Staphylococcus* species), fungi may also cause superficial or deep eyelid lesions.

Types

Necrotizing fasciitis of the eyelids and periorbital area due to *Cryptococcus neoformans* was reported in a young man after a trivial trauma by a wooden splinter (Doorenbos-Bot et al. 1990), while an eyelid nodule and ulcerative lesions have been reported to constitute a sentinel lesion of disseminated cryptococcosis in a patient with AIDS (Coccia et al. 1999).

Use of broad-spectrum antibacterials or immunosuppressive agents may predispose to spread of infection from a focus, resulting in the occurrence of an eyelid lesion due to a *Candida* sp. (Alvarez and Tabbara 1996). Ulceration begins at the base of an eyelash; small granulomata appear at its edge, and vesicles and pustules may also be present. In a study of 407 patients with chronic severe ulcerative blepharitis, Huber-Spitzy et al. (1991) noted the occurrence of positive cultures for *Candida* spp. in 47 (12 percent); most of these patients also had atopic dermatitis.

Malassezia spp. (formerly *Pityrosporum orbiculare* and *Pityrosporum ovale*) (Ashbee and Evans 2002) are superficial fungi that may be associated with seborrheic blepharitis and pityriasis versicolor, a chronic mild skin infection sometimes found around the eyebrows and eyelids. When lid scrapings from 40 patients with active seborrheic or mixed seborrheic/staphylococcal

blepharitis were subjected to microbiological investigations, yeasts with the morphology of *Malassezia* spp. were detected by direct microscopic examination in the scrapings of 39 of the 40 patients, while fungi were isolated from those of about half the patients (Nelson et al. 1990).

Lesions caused by the dermatophytes begin as erythematous scaly papules that slowly enlarge; healing simultaneously occurs in the central, paler area. Infections caused by species of *Microsporum* and *Trichophyton* result in the hair breaking at the level of the skin surface.

Although the eyelid is generally considered to be the most common site of ocular infection due to *Blastomyces dermatitidis* (Safneck et al. 1990; Slack et al. 1992), Bartley (1995) reported that only one of 79 patients with systemic blastomycosis seen by him had such lesions. The lesions may arise due to contiguous spread from facial lesions, or due to hematogenous dissemination from a pulmonary lesion. Small abscesses may be visible around the eyelashes. These later form granulomatous ulcers with thick crusts and an underlying purplish discoloration of the skin. Healing of the lesions may lead to severe cicatrization and ectropion formation (Slack et al. 1992). Conjunctival lesions generally occur due to contiguous spread from eyelid lesions, but may also occur as separate entities (Slack et al. 1992).

Eyelid lesions, alone or in association with corneal and conjunctival lesions, have been found to occur in more than 50 percent of reported cases of ocular paracoccidioidomycosis (Belfort et al. 1975; Silva et al. 1988; Burnier and Sant' Anna 1997). The palpebral lesion starts as a papule, usually close to the lid border, and grows and ulcerates in the center. The base of the ulceration reveals fine hemorrhagic punctate and elevated, thickened and hardened borders. The lesions evolve toward palpebral coloboma, with loss of the eyelashes.

Rhinosporidiosis of the lid margins is a rare occurrence (Reidy et al. 1997).

Diagnosis

Infections due to dermatophytes may exhibit fluorescence when exposed to a Wood's lamp. The hyphae or yeast cells of fungi causing eyelid lesions can be demonstrated by examination of a 10 percent potassium hydroxide mount or a Gram-stained smear of scrapes from the eyelids.

Therapy

Several therapeutic regimens have been recommended for mycoses of the eyelids (Alvarez and Tabbara 1996; Behrens-Baumann 1999), but the basis on which these suggestions have been made is not clear.

For infections due to the dermatophytes, terbinafine, itraconazole, or local antifungal drugs (active ingredients being combinations of fatty acids and salicylic acid) probably suffice (Ellis 1985). In one patient, lesions of the eyebrow due to *Trichophyton rubrum* were found to have disappeared almost entirely after 3 weeks of oral itraconazole therapy (Hiruma et al. 1991).

Nelson et al. (1990) reported that when topical 2 percent ketoconazole cream with lid hygiene was used to treat seborrheic blepharitis (due to *Malassezia* spp.) and mixed seborrheic/staphylococcal blepharitis, patients receiving ketoconazole more frequently had normal or markedly improved lids after treatment than did a control group of patients receiving only placebo and lid hygiene.

For infections due to *Candida* spp., topical agents, including ointments of nystatin (100 000 units/g), ketoconazole (2 percent cream), miconazole (2 percent), clotrimazole (1 percent) or econazole (1 percent), and oral ketoconazole (200–400 mg/day) are reportedly effective (Ellis 1985), while oral fluconazole (150 mg) once or twice weekly for 2–3 months has also been reported to be useful for such infections(Alvarez and Tabbara 1996). Oral ketoconazole twice daily (100 mg/day) with topical miconazole ointment for 6 weeks has been recommended for treatment of blepharitis due to *Candida* spp. (Huber-Spitzy et al. 1991).

Lesions of the eyelid in a patient with disseminated infection due to *Cryptococcus neoformans* var. *neoformans* was controlled (although there were occasional recurrences) by a combination of surgical excision and intravenous amphotericin B (Coccia et al. 1999).

Verrucous lesions of the eyelid due to *Blastomyces dermatitidis* were reported to resolve with a combination of antifungals (potassium iodide, intravenous amphotericin B) and surgery (Barr and Gamel 1986); oral fluconazole (150 mg) once or twice weekly for 2–3 months has also been reported to be useful (Alvarez and Tabbara 1996). Itraconazole is an alternative.

Papular lesions of the eyelids due to *Paracoccidioides brasiliensis* were reported to respond to intravenous amphotericin B, alone or in combination with oral ketoconazole, without any surgery being required (Silva et al. 1988).

Lesions of the eyelid due to *Rhinosporidium seeberi*, which are rare, require excision.

Deep infections of the eyelids, which may occur in infections due to the thermally dimorphic fungi or in infections due to species of *Aspergillus*, *Candida*, or *Cryptococcus*, must be treated with drugs administered systemically; intravenous amphotericin B is usually the treatment of choice, although oral ketoconazole, itraconazole, or fluconazole may be considered in milder infections (Ellis 1985; Grant and Clissold 1989; Alvarez and Tabbara 1996). In one patient, preseptal cellulitis

due to a *Trichophyton* spp. was described to have completely resolved following two courses of oral itraconazole (100 mg/day) (Velazquez et al. 2002).

MYCOTIC DACRYOCANALICULITIS

Fungi, such as *Alternaria* spp., *Aspergillus fumigatus* and other *Aspergillus* spp., *Candida* spp., dermatophytes, *Fusarium* spp., *Penicillium* spp., *Scopulariopsis* spp., and *Sporothrix schenckii*, have been reported as causes of canaliculitis (Levin et al. 1996; Behrens-Baumann 1999), although the significance of some of these isolates is doubtful since they do not appear to satisfy the criteria described earlier (McGinnis 1980). Most of the clinical features described, as well as the surgical procedures recommended, are for dacryocanaliculitis in general, and are not necessarily specific for fungal infection.

Dacryocanaliculitis usually manifests as persistent unilateral epiphora (watering), with an itching sensation; there may be associated unilateral mucopurulent conjunctivitis. The eyelid is usually red and swollen in the area of the affected canaliculus, with associated unilateral conjunctivitis (conjunctival follicles may be present); reddening and swelling of the canaliculus itself (the opening is dilated and the edges are elevated and inflamed); a mucopurulent discharge and white, yellow, or brown concretions (dacryoliths) in the lacrimal punctum may also be observed (Vecsei et al. 1994). The remainder of the lacrimal passages is patent, and there is no preauricular lymphadenopathy. Local environmental factors in the canaliculus, such as stasis arising out of congenital diverticula, may predispose to these infections.

Pavilack and Frueh (1992) underscored the importance of thorough curettage as the most effective treatment for chronic canaliculitis, although their recommendations were not based on the study of specific actinomycotic or fungal causes of canaliculitis. Essentially, following topical and local anesthesia, the punctum is dilated and a small curette is introduced. If there is extensive ectasia and retention of concretions in diverticuli, a canaliculotomy may be necessary (Behrens-Baumann 1999). Following curettage (Pavilack and Frueh 1992), the canaliculus is thoroughly irrigated to remove any remaining fragments, identify unrecognized pockets of retained debris, and ensure that the distal part of the drainage system is patent.

Mycotic dacryocanaliculitis is reported to be usually satisfactorily treated by topical administration of 5 percent natamycin or by topical application and local syringing of the canaliculi and sac with amphotericin B solution (1.5–8 mg/ml) or nystatin solution (25 000–100 000 units/ml) (Wilson and Ajello 1998; Behrens-Baumann 1999); however, the basis for these recommendations is not clear. If medical therapy fails, surgery (canaliculotomy) is required. All material removed is stained and cultured, and the canaliculus is then syringed with the medications. Silicone intubation may be required for reconstruction of the canaliculus.

In a study on 40 patients with canaliculitis, Vecsei et al. (1994) reported that only 10 percent were cured by medical treatment alone and that 40 percent showed a recurrence; by contrast, 80 percent of patients who underwent canaliculotomy were cured. These results suggest that surgical treatment of canaliculitis, in combination with medical therapy, may yield better results than medical therapy alone.

MYCOTIC DACRYOCYSTITIS

Dacryocystitis, which is an infection of the lacrimal sac (Brook and Frazier 1998), is the most common infection of the entire lacrimal apparatus, and generally arises due to the stasis accompanying obstruction of the nasolacrimal duct; there are several possible causes (Behrens-Baumann 1999). Dacryocystitis may be acute or chronic, but fungi usually do not cause acute dacryocystitis. Chronic dacryocystitis usually arises following partial or complete obstruction at a single site within the lacrimal sac or within the nasolacrimal duct; infection generally follows obstruction, and does not cause it (Kalavathy et al. 1986).

Bacteria (especially aerobic and facultative anaerobic bacteria) may be the etiologic agents of infection in more than 90 percent of patients with acquired dacryocystitis, fungi accounting for only about 5 percent of infections (Kalavathy et al. 1986; Brook and Frazier 1998). However, in congenital dacryocystitis, fungi may account for almost 14 percent of infections (Ghose and Mahajan 1990). The genera of fungi that have been implicated as causes of dacryocystitis include *Acremonium* spp., *Aspergillus* spp., *Candida* sp., *Paecilomyces* spp., *Rhinosporidium seeberi*, dermatophytes, and *Sporothrix schenckii* (Henig et al. 1973; Kalavathy et al. 1986; Ghose and Mahajan 1990; Purgason et al. 1992; Levin et al. 1996; Reidy et al. 1997; Kristinsson and Sigurdsson 1998; Wilson and Ajello 1998; Behrens-Baumann 1999); however, the significance of some of these species as actual causes of dacryocystitis is uncertain, if one analyzes the descriptions per the criteria described earlier (McGinnis 1980). Infections due to *Sporothrix schenckii* and *Acremonium* spp. are reported to manifest as chronic suppurative dacryocystitis, with preauricular and submaxillary lymphadenitis and possible abscess formation. On the other hand, species of *Aspergillus*, *Candida* and *Paecilomyces*, *Rhinosporidium seeberi*, and the dermatophytes may cause chronic granulomatous dacryocystitis (Purgason et al. 1992; Levin et al. 1996; Kalavathy et al. 1998; Behrens-Baumann 1999). With partial or complete obstruction of the nasolacrimal duct, a laminated concretion (dacryolith) may develop in the lacrimal sac.

While epiphora is frequently the only clinical finding in patients with chronic dacryocystitis, there may also be

lid edema, conjunctival infection, and a swelling in the medial canthus; pressure over the area usually results in a purulent discharge through the lower punctum (Kalavathy et al. 1986). Kristinsson and Sigurdsson (1998) described a patient in whom *Aspergillus fumigatus* caused plugging of the lacrimal sac, leading to extreme tenderness of the lacrimal sac, epiphora, and discharge from the lacrimal punctum. Krishnan et al. (1986) described the occurrence of a diverticulum of the lacrimal sac in association with rhinosporidiosis while, more recently, Kalavathy et al. (1998) described rhinosporidiosis of the lacrimal sac in two patients in whom bloodstained epiphora (due to the extreme fragility of the lesion) was the presenting complaint.

Management of this condition is by dacryocystectomy (for rhinosporidiosis), where the lacrimal sac is removed in toto, or dacryocystorhinostomy, where the patency of the nasolacrimal duct is restored; dacryoliths, if present, should be surgically removed and dacryocystorhinostomy performed. Chronic mycotic dacryocystitis in six patients was found to resolve completely following dacryocystectomy (Kalavathy et al. 1986), while some patients with congenital mycotic dacryocystitis were reported to respond satisfactorily to topical antifungals, probing, and syringing (Ghose and Mahajan 1990). Dacryocystitis due to *Candida albicans* was reported to resolve completely following surgery, alone or in combination with topical miconazole and natamycin therapy (Purgason et al. 1992). Dacryocystitis following lacrimal sac plugging due to *Aspergillus fumigatus* was relieved by the simple procedure of removing the plug after opening the lacrimal sac; dacryocystorhinostomy was not performed, and the patient was symptom-free one year after the procedure (Kristinsson and Sigurdsson 1998). Recently, minimally invasive, transnasal dacryocystorhinostomy surgery employing endoscopic and laser technologies has been introduced. Postoperative infection could probably be reduced by intraoperative or postoperative antifungal therapy.

MYCOTIC DACRYOADENITIS

Acute fungal infections of the lacrimal gland are rare; zygomycetes can cause a necrotizing dacryoadenitis in the setting of contiguous sino-orbital disease(Behrens-Baumann 1999). Chronic granulomatous dacryoadenitis can be caused by certain filamentous fungi (Wilson and Ajello 1998; Behrens-Baumann 1999). Such an infection is treated by using systemic antifungal agents.

MYCOTIC CONJUNCTIVITIS

Under normal circumstances, fungi are transient inhabitants of the normal conjunctival sac (Williamson et al. 1968; Brinser and Burd 1986). However, the unrestricted use of topical antibacterials or corticosteroids may predispose to fungal infection (Williamson et al. 1968; Ben Ezra 1994). Acute conjunctivitis due to fungi appears to be uncommon. In a microbiological study of 102 patients with clinically diagnosed acute conjunctivitis (Boralkar et al. 1989), fungi were isolated from only 14 samples, and here also the criteria used to define significant growth of fungi from these 14 samples were not stated. Severe necrotizing granulomatous conjunctivitis due to *Coccidioides immitis* has been described in a patient who had received aggressive treatment with corticosteroids by various routes (Maguire et al. 1994).

The clinical manifestations of mycotic conjunctivitis are described as being dependent on the fungi involved (Ben Ezra 1994; Behrens-Baumann 1999), but the basis for these observations is unclear. The manifestations described include:

- simple acute or subacute superficial epithelial conjunctivitis due to *Candida* spp. (purulent infection), dermatophytic fungi (chronic lesions) and *Malassezia* spp. (catarrhal conjunctivitis)
- nodular conjunctivitis, with associated deep lesions and local lymphadenopathy due to *Sporothrix schenckii*
- follicular conjunctivitis due to *Blastomyces dermatitidis*, *Coccidioides immitis*, or *Paracoccidioides brasiliensis*, or chronic conjunctivitis with black conjunctival secretions due to *Aspergillus niger*.

Treatment of this condition can be difficult. Local therapy with topical antifungals may suffice if only the conjunctiva is involved, but systemic therapy is also needed if the eyelids are involved (Ellis 1985). In one patient, severe necrotizing granulomatous conjunctivitis due to *Coccidioides immitis* was finally controlled only after aggressive debridement of the affected area and months of topical amphotericin B and oral fluconazole therapy (Maguire et al. 1994).

Conjunctival rhinosporidiosis

Most reported ocular lesions due to rhinosporidiosis have occurred in hot, dry, climatic regions, with the occasional case from temperate zones (Reidy et al. 1997). While nasal lesions predominate in endemic areas, a predominance of ocular lesions is believed to indicate an epidemic (Vukovic et al. 1995). Ocular rhinosporidiosis most frequently manifests as single or multiple polypoidal outgrowths of the palpebral conjunctiva; these are pink or red, granular or lobulated (occasionally flattened), sessile or stalked, and attached to the upper or lower fornix or the tarsal conjunctiva (Ukety et al. 1992; Gaines et al. 1996; Pe'er et al. 1996; Reidy et al. 1997; Shrestha et al. 1998). Conjunctival rhinosporidiosis with associated scleral melting and staphyloma formation, a rare occurrence, was recently reported in three patients in India, with the lesions manifesting as gray–white spherules without polyps (Castelino et al.

2000). The occurrence of rhinosporidiosis of the lid margins, canaliculus, and lacrimal sac has been described earlier.

Rhinosporidial lesions of the eye are usually unilateral and solitary, and cause no discomfort to the patient; however, there may be increased lacrimation, discharge, tenderness of the lids, and photophobia. A clinical diagnosis of ocular rhinosporidiosis is justified if there are similar, extremely friable lesions elsewhere in the body presenting as small, white dot-like structures against a red background (the cysts embedded in the vascular tissue bed). However, a focal lesion on the conjunctiva, eyelid, or sclera needs to be differentiated from a cystic inclusion or adenoma of the various glandular structures, pterygium, pedunculated granuloma due to retained foreign body or end-stage chalazion (Prevost et al. 1980).

Since all attempts to cultivate *Rhinosporidium seeberi* in artificial culture media have been unsuccessful, histopathology is required to establish the diagnosis. The typical histological picture is that of a granuloma with marked inflammatory cell infiltrate (Rippon 1988), but a chronic nongranulomatous type of inflammation has also been described (Pe'er et al. 1996). All stages of the life cycle can be seen in excised tissue, from small trophocytes to large sporangia-containing sporoblasts. Hematoxylin and eosin staining is sufficient to demonstrate the distinctive spherical bodies (spherules or sporangia), which vary in size from 6 to 30 μm (Figure 9). The presence of such well-defined spherical bodies of varying size in a rather dense stroma covered by hyperplastic epithelium is a distinctive feature (Rippon 1988); however, these structures need to be differentiated from the spherules of *Coccidioides immitis*. Serological tests have not been found useful for the diagnosis of the condition.

No drug treatment has proven effective for ocular rhinosporidiosis. This condition is treated by surgical excision of the lesions.

MYCOTIC KERATITIS (KERATOMYCOSIS)

Frequency of occurrence

Mycotic keratitis, a suppurative, usually ulcerative, fungal infection of the cornea, may be responsible for more than 50 percent of all cases of ocular mycoses (Srinivasan et al. 1991) and of all patients with culture-proven microbial keratitis (Hagan et al. 1995), especially in tropical and subtropical environments. This condition apparently occurs more frequently in developing countries (e.g. India) than in the developed world (e.g. the USA). In one study in southern India, 139 patients with culture-proven mycotic keratitis were observed in a period of just 3 months (Srinivasan et al. 1997), whereas in the USA, 125 patients with culture-proven mycotic keratitis were seen over a 10-year period in southern Florida (Rosa et al. 1994) and just 24 such patients over a 9-year period at Philadelphia (Tanure et al. 2000). Although a high incidence of mycotic keratitis can be expected in countries with similar annual rainfall and temperature range, this is not always so and also appears to depend on the extent of urbanization (Houang et al. 2001).

Types

In terms of occurrence, risk factors, and therapeutic approaches, two basic types of this condition are commonly seen, namely, keratitis due to filamentous fungi and keratitis due to yeast-like and related fungi (Jones 1980); a third type, keratitis due to thermally dimorphic fungi such as *Blastomyces dermatitidis* (Rodrigues and Laibson 1973) and *Paracoccidioides brasiliensis* (Silva et al. 1988) occurs rarely. There appears to be a strong geographical influence on the occurrence of the different forms of mycotic keratitis. A review of the data from 39 studies on microbial keratitis or mycotic keratitis reported in the literature between 1976 and 2001 (23 of the studies had been performed in Asia, six in North America and five in Africa) revealed that the proportion of corneal ulcers caused by filamentous fungi tends to increase towards tropical latitudes, whereas in more temperate climates, fungal ulcers appear to be uncommon and to be more frequently associated with *Candida* spp. than filamentous fungi (Leck et al. 2002).

Filamentous fungi are the principal causes of mycotic keratitis in most parts of the world. In 29 of the 39 studies reported between 1976 and 2001, and in another two studies published in 2002 (Gopinathan et al. 2002; Leck et al. 2002), either *Aspergillus* spp. or *Fusarium* spp. were the commonest isolates. The high proportion of corneal infections caused by *Aspergillus* spp. in drier climates may be because spores of *Aspergillus* spp. can tolerate hot, dry weather conditions (Khairallah et al. 1992); however, *Aspergillus* spp. may also predominate in more temperate latitudes (Leck et al. 2002). Dematiaceous fungi, such as *Curvularia* spp., have been reported to be the third most important cause of keratitis in a number of studies (Srinivasan et al. 1997; Garg et al. 2000; Gopinathan et al. 2002; Leck et al. 2002).

Keratitis due to yeasts and yeast-like fungi is most frequently caused by *Candida albicans* (Liesegang and Forster 1980; Tanure et al. 2000); less frequent causes include *Candida parapsilosis*, *Candida tropicalis*, and *Cryptococcus neoformans* var. *neoformans* (see Table 3). Since *Candida albicans* is an ubiquitous commensal of mucous membranes in humans with no geographical dominance, keratitis due to this organism tends to occur more frequently in areas where traumatic keratitis is uncommon, but where other predisposing factors are important (Jones 1980). *Candida albicans* was

reported to be the commonest fungal species isolated from culture-proven mycotic keratitis in southern California (Ormerod et al. 1987) and in Philadelphia (Tanure et al. 2000), but species of *Candida* accounted for only 12.5 percent of isolates in culture-proven mycotic keratitis in Miami (Rosa et al. 1994). Species of *Candida* and related fungi have been infrequent isolates in most recent studies performed in tropical countries (Dunlop et al. 1994; Gonawardena et al. 1994; Hagan et al. 1995; Srinivasan et al. 1997; Gopinathan et al. 2002; Leck et al. 2002), possibly due to the predominance of livelihoods, such as agriculture, which carry a higher risk for occurrence of trauma-related keratitis caused by filamentous fungi than for keratitis due to *Candida albicans*.

Risk factors

Although the risk factors for microbial keratitis, in general, are well-known (Rosa et al. 1994; Tanure et al. 2000), there have been few attempts to identify specific risk factors for mycotic, as opposed to bacterial, keratitis. In one study in Bangladesh, 35 percent of patients with mycotic keratitis and 52 percent of patients with bacterial keratitis reported antecedent ocular trauma, while dacryocystitis was noted in 12 percent of bacterial and 4 percent of mycotic keratitis (Dunlop et al. 1994). The data derived from a retrospective case–control study in Singapore suggested that mycotic keratitis (principally due to *Fusarium* spp. and *Aspergillus* spp.) was frequently associated with mechanical ocular trauma, whereas bacterial keratitis (principally due to *Pseudomonas aeruginosa*) was more likely to be related to contact lens wear and preexisting ocular diseases; also, antecedent topical corticosteroid therapy (which is traditionally believed to be a specific risk factor for mycotic keratitis) appeared to predispose more frequently to bacterial (38 percent), than to fungal (25 percent), keratitis (Wong et al. 1997).

Certain conditions may predispose more frequently to filamentous fungal keratitis than to keratitis caused by yeast-like fungi. Filamentous fungal keratitis, especially that due to *Fusarium* spp. or *Aspergillus* spp., appears to occur most commonly in healthy young men engaged in agricultural work or outdoor occupations. Trauma is the principal risk factor in 44–55 percent of such patients; various traumatizing agents have been reported, including vegetable matter, mud or dust particles, paddy grain, the swish of a cow's tail, tree branches, and metallic foreign bodies. Prolonged use of topical corticosteroids or antibacterials, diabetes mellitus, preexisting ocular diseases, and contact lens wear, preexisting allergic conjunctivitis or vernal keratoconjunctivitis, and the occupation of onion harvesting, are less frequently encountered factors in filamentous fungal keratitis (Vajpayee et al. 1990; Rosa et al. 1994; Panda et al. 1997; Gupta et al. 1999; Lin et al. 1999; Xie et al. 2001; Gopinathan et al. 2002). Trauma and prior use of corticosteroids have also been noted to be the most frequent risk factors in keratitis due to *Curvularia* spp. (Wilhelmus and Jones 2001). Seasonal variations that have been observed in the incidence of filamentous fungal keratitis, and in the predominant genera of fungi isolated from such cases, have been linked to environmental factors, such as humidity, rainfall, and wind, and also to the harvest (Cuero 1980; Liesegang and Forster 1980; Thomas 1990; Rosa et al. 1994). By contrast, in a study at Philadephia (Tanure et al. 2000) in which *Candida albicans* was the most common isolate (46 percent), the three most common risk factors were found to be chronic ocular surface disease, contact lens wear, and use of topical corticosteroids. A case–control study to compare the relative contribution of different risk factors in determining whether a patient develops keratitis due to filamentous fungi, or that due to yeast or yeast-like fungi, would be of great value.

Diagnosis

A rapid and accurate diagnosis of mycotic keratitis improves the chances of a complete recovery. A detailed clinical history should first be obtained. This should include details of possible predisposing factors (trauma, use of contact lenses), prior therapy with antibacterials, corticosteroids or other compounds, and preexisting ocular disease (allergic conjunctivitis, lagophthalmos). The clinician should then look for ocular or systemic defects that may have predisposed to the keratitis, since these require correction. Symptoms are usually similar to those seen in other types of keratitis, but, perhaps, more prolonged in duration (5–10 days).

Filamentous fungal keratitis, which may involve any area of the cornea, usually presents with firm (sometimes dry) elevated necrotic slough (Figure 11a), 'hyphate' lines extending beyond the ulcer edge into the normal cornea, and multifocal granular (or feathery) gray-white 'satellite' stromal infiltrates (Figure 11b); an 'immune ring,' minimal cellular infiltration in the adjacent stroma, mild iritis, and an endothelial plaque and hypopyon may also occur. Rosa et al. (1994) observed irregular feathery margins in 62.4 percent, elevated borders (52 percent), dry rough texture (47 percent), satellite lesions (41 percent), and Descemet's folds in 40 percent of 125 patients with culture-proven mycotic keratitis. There may be variations from this pattern depending on the etiologic agent (Wilhelmus and Jones 2001). *Fusarium solani* usually causes a severe infection (Figure 11c), with perforation, deep extension, and malignant glaucoma supervening (Verma and Tuft 2002). Keratitis due to *Aspergillus* spp. is generally believed to be less severe than keratitis due to *Fusarium* (Thomas et al. 1988; Thomas and Rajasekaran 1988),

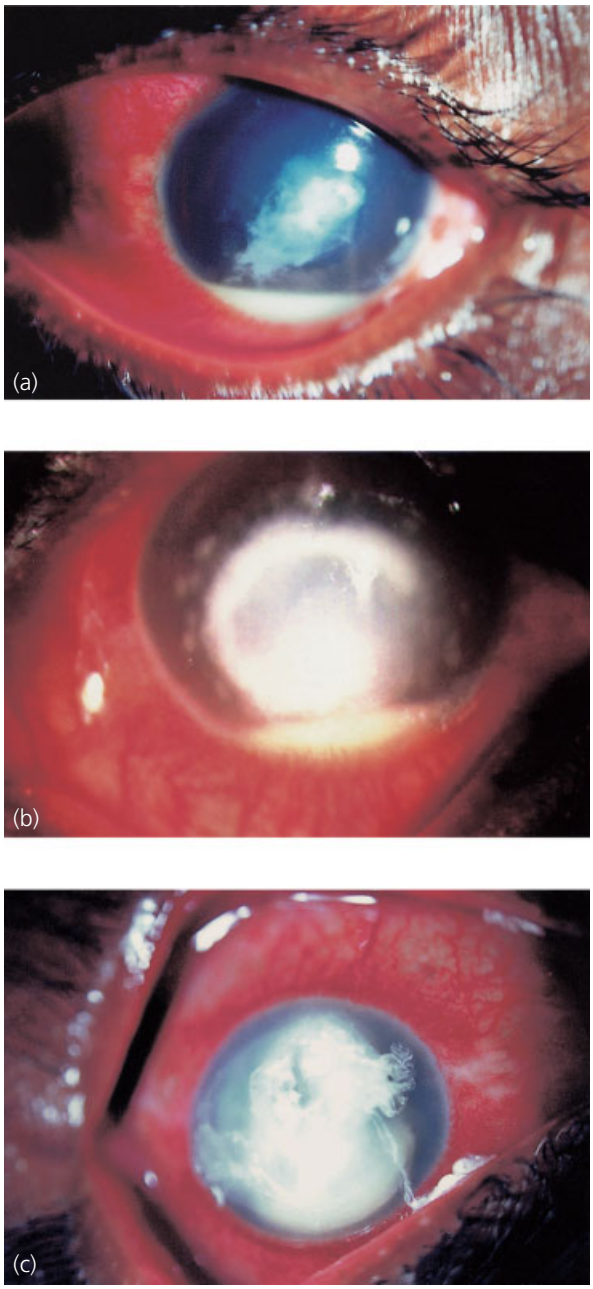

Figure 11 (a) *Mycotic keratitis due to* Fusarium solani *exhibiting elevated necrotic slough.* **(b)** *Mycotic keratitis due to* Aspergillus flavus *exhibiting 'satellite' lesions.* **(c)** *Severe mycotic keratitis due to a* Fusarium *sp.*

although one group of workers (Vemuganti et al. 2002) noted that a high percentage of patients with *Aspergillus* keratitis ultimately required therapeutic penetrating keratoplasty due to nonresponsiveness to medical therapy. In keratitis due to certain dematiaceous hyphomycetes (species of *Curvularia*, *Bipolaris*, or *Exserohilum*), a persistent, low-grade, smoldering keratitis, with minimal structural alteration and pigmentation, may occur (Garg et al. 2000). Fungi that have been found to cause severe forms of keratitis clinically, which respond poorly to medical therapy, include *Lasiodiplodia theobromae* (Borderie et al. 1997; Thomas et al. 1998), *Pythium insidiosum* (Virgile et al. 1993; Thianprasit et al. 1996), and *Scedosporium apiospermum* (*Pseudallescheria boydii*) (Zapater and Albesi 1979; Wu et al. 2002). Chronic, severe, filamentous fungal keratitis may resemble bacterial suppuration, and may involve the entire cornea (Klotz et al. 2000). The stromal keratitis caused by *Candida albicans* and related fungi resembles bacterial keratitis, with an overlying epithelial defect, a more discrete infiltrate, and slow progression; such ulcers frequently occur in eyes with preexisting corneal disease, and in areas of exposure, such as inferocentrally, at the junction of the superior two-thirds and inferior one-third of the cornea (O'Day and Burd 1994). Keratitis due to a zygomycete, such as *Rhizopus* spp. (Rosa et al. 1994), or *Absidia corymbifera* (Marshall et al. 1997), which is a rare occurrence, runs a very fulminant course and is unresponsive to medical therapy, so that penetrating keratoplasty is required within a few days of presentation.

The clinical suspicion of mycotic keratitis can sometimes be confirmed by noninvasive means using confocal microscopy, an imaging technique that allows optical sectioning of almost any material, with increased axial and lateral spatial resolution, and better image contrast than conventional slit-lamp microscopy. In clinical keratitis due to an *Aspergillus* sp., fungal hyphae were imaged as high-contrast filaments, 60–400 μm long, and 6 μm in width (Winchester et al. 1997), while in another patient with keratitis due to *Fusarium solani* (Florakis et al. 1997), in vivo scanning slit confocal microscopy helped to first establish the diagnosis, then to demonstrate progression of the disease, and finally to confirm the success of penetrating keratoplasty. This technique has been used, in conjunction with culture, in establishing a diagnosis of mycotic keratitis (Xie et al. 2001; Verma and Tuft 2002). The potential benefits of confocal microscopy in demonstrating the presence of fungal hyphae in vivo within the human cornea by noninvasive means need to be weighed against limitations such as limited resolution of the microscope, difficulty in performing serial examinations, and the lack of a distinctive morphology of some pathogens.

For the microbiological diagnosis of mycotic keratitis, corneal material (as scrapings or biopsy material) is the specimen of choice. Prior to performing a corneal scraping, it is generally recommended that material be collected from the ipsilateral and contralateral lid and conjunctiva (by sterile cotton-tipped or calcium alginate swabs) to ensure that the organisms isolated on the corneal media have not come from the transient commensal fungal flora of the lid margins or conjunctival sac (Jones et al. 1981). However, Sharma et al. (1994) have questioned the rationale for performing such cultures of swabs from the lids and conjunctivae, stating that in their experience, a correlation between

the corneal and conjunctival isolate occurred in only 3 percent of cases; these workers opined that processing of such samples might, in fact, provide misleading data.

Corneal scrapings are obtained by using an instrument (platinum spatula, Beaver blade, Bard-Parker knife no. 15, blunt cataract knife) to debride material from the base and edges of the ulcerated part of the cornea (Agrawal et al. 1994); this should be done several times to obtain as much material as possible. The blade or spatula may be reused if a sterile medium has been streaked, but must be changed (the spatula can be flamed) if the instrument has made contact with an unsterile slide (Agrawal et al. 1994). Although cotton-tipped swabs do not seem to be a useful means of debriding the necrotic corneal slough, calcium alginate swabs (premoistened with tryptone soy broth), when used for the debridement, may facilitate recovery of fungi in culture (Jacob et al. 1995).

If corneal scrapings do not yield positive results, a corneal biopsy may aid diagnosis since a greater quantum of tissue can be obtained from a greater depth of the cornea. A simple method is to perform free dissection of the corneal lamellae by a sharp surgical knife; here, corneal perforation is a distinct risk. Another method involves removal of the epithelium and necrotic debris overlying the suppurated area and incision of the corneal stroma by a Bard-Parker no. 15 blade and corneal forceps to about one half the corneal thickness (Ishibashi et al. 1987). A corneal trephine may be used to define the precise diameter and depth (0.2–0.3 mm) of corneal tissue that is to be removed (Lee and Green 1990; Kompa et al. 1999). The biopsies may be relatively superficial (keratectomy) or deep. The biopsied tissue may be stained by ink-potassium hydroxide (Ishibashi et al. 1987) or lactophenol cotton blue (Kompa et al. 1999). Several experimental studies have unequivocally highlighted the value of corneal biopsy samples in diagnosis of keratitis due to *Aspergillus fumigatus*, *Candida albicans*, or *Fusarium solani* (Ishibashi and Kaufman 1986b; Ishibashi et al. 1987). The results obtained in a clinical setting are less clearcut. There is anecdotal evidence, in small numbers of patients, to support the use of corneal biopsy samples in diagnosis of mycotic keratitis (Ishibashi and Kaufman 1986b; Brooks and Coster 1993; Rosa et al. 1994; Kompa et al. 1999). However, Lee and Green (1990) reported that only nine of 42 samples submitted from patients with clinically evident infectious ulcerative keratitis were positive for infectious agents (including the presence of fungi in three of the nine positive samples).

While direct microscopic examination of corneal scrapes or corneal biopsy samples permits a rapid presumptive diagnosis of mycotic keratitis, it is generally not considered possible to identify the fungal genus involved. However, the occurrence of adventitious sporulation (presence of conidial structures) in tissue samples, including corneal material, may aid in the differentiation of genera of hyaline filamentous fungi, such as *Acremonium*, *Fusarium*, and *Paecilomyces* (Liu et al. 1998). Examination of a wet preparation (using 10 percent potassium hydroxide, ink-potassium hydroxide, or lactophenol cotton blue), a smear stained by the Gram method (Figure 12a) or Giemsa method, and a smear stained by special fungal stains, such as methenamine silver, periodic acid–Schiff, calcofluor white (Figure 12b), may yield valuable results. The corneal material should be spread out as thinly as possible on the microscope slides to facilitate easy visualization of the fungal structures.

In culture-proven mycotic keratitis, sensitivities of 72.2 percent (Xie et al. 2001) to 91 percent (Gopinathan et al. 2002) for potassium hydroxide mounts, 31.6 percent (Panda et al. 1997) to 98 percent (Dunlop et al. 1994) for Gram-stained smears, 27 percent (Rosa et al. 1994) to 85 percent (Gopinathan et al. 2002) and 56 percent (Upadhyay et al. 1991) to 86 percent (Forster et al. 1976) for smears stained by Gomori methenamine silver, and 91.4 percent for calcofluor white-stained smears (Gopinathan et al. 2002) have been reported.

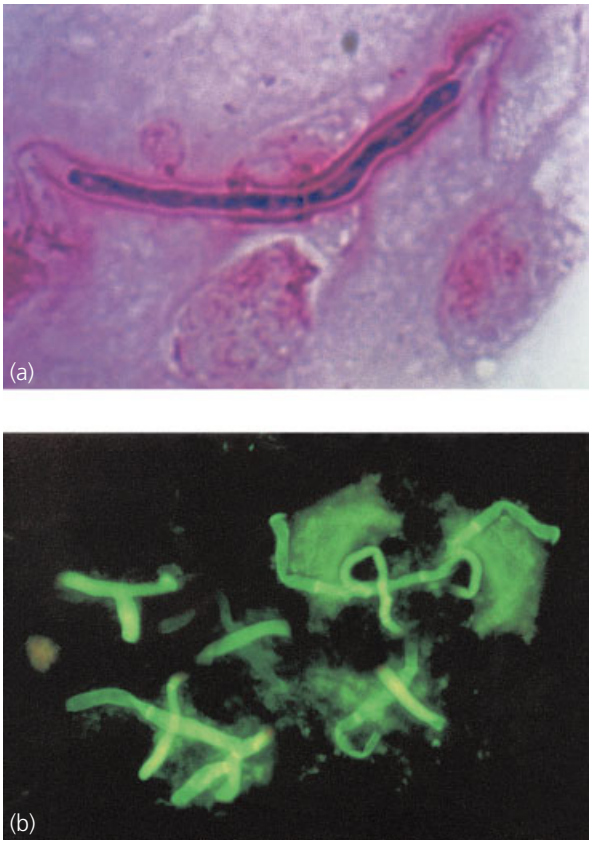

Figure 12 (a) *Photomicrograph of fungal hyphae in corneal scrape material. Cytoplasm is stained, cell wall and cross-walls are unstained. Gram stain; magnification ×1 200.*
(b) *Photomicrograph of fungal hyphae in corneal scrape material. Fungal hyphae fluoresce greenish-yellow against a dark background. Calcofluor white stain; magnification ×400*

Lactophenol cotton blue-stained mounts of corneal scrapes (Figure 5) have been found to yield positive results in about 78 percent of culture-proven mycotic keratitis (Thomas et al. 1991b; Sharma et al. 1998), while acridine orange-stained smears yielded positive results in 76 percent of clinically suspected cases of mycotic keratitis (Kanungo et al. 1991). A fluorescent Gram-stain technique permitted a rapid presumptive diagnosis of mycotic keratitis in five patients, with the diagnosis being confirmed by culture in all five (Roychoudhury et al. 1997); this stain also detected fungi in the vitreous biopsy of one patient with culture-proven *Aspergillus flavus* endophthalmitis. However, this staining technique has not acquired widespread use. When combined potassium hydroxide–calcofluor white staining was used to detect fungi in corneal scrapings from 114 patients with early keratitis, and 363 patients with advanced keratitis, a sensitivity of 61.1 percent and specificity of 99.0 percent in early keratitis, and a sensitivity of 87.7 percent and specificity of 83.7 percent in advanced keratitis was achieved; while the predictive values were high for potassium hydroxide–calcofluor white in the detection of fungus, this technique yielded false positives in 16.3 percent of patients with advanced keratitis (Sharma et al. 2002). All these results indicate that direct microscopic examination of corneal material permits a rapid presumptive diagnosis of mycotic keratitis, and correlates well with positive results in culture.

CULTURE

A diagnosis of mycotic keratitis is confirmed by isolation of fungi from corneal scrapes or biopsies which are inoculated onto the surface of solid media by making rows of 'C' streaks (two rows from each scraping), with only growth on the 'C' streaks being deemed significant (Figure 13), or by immersing the tip of the spatula, loop, or swab into broth (liquid) media. Commonly used culture media include Sabouraud glucose neopeptone agar (Emmons' modification, neutral pH), which is incubated at 25°C, 5 percent blood (preferably sheep blood) agar (25°C and 37°C), brain heart infusion broth (25°C), and thioglycollate broth (25–30°C) (O'Day and Burd 1994). Using these different media, fungi grew out in culture within 2 days in 54 percent, 3 days in 83 percent, and 1 week in 97 percent of patients with mycotic keratitis; 90 percent of scrapings yielded a positive initial culture (Rosa et al. 1994). Chocolate agar (Rosa et al. 1994), cystine tryptone agar (Thomas 1994), and rose bengal agar (P.A. Thomas, unpublished observations) are other media that can be used. Antibacterial compounds, such as chloramphenicol (40 μg/ml) or a penicillin–streptomycin combination, are usually incorporated in the media to suppress bacterial growth, but cycloheximide must never be used since it may suppress most ocular fungal pathogens (O'Day and Burd 1994). While some investigators(Upadhyay et al. 1991) advocate the use of liquid-shake cultures to facilitate recovery of ocular fungi, others (Srinivasan et al. 1997) discourage their use since equivocal results may occur. Although fungi are usually recovered in culture within 3–4 days, culture media may need to be kept for up to 4–6 weeks. 'Sham cultures' are maintained to ensure that there is no contamination, either from the environment or media, during sample collection. A fungal strain recovered in culture from corneal material is considered significant if isolated more than once, or in two or more media, or on multiple 'C' streaks of one medium with fungal hyphae or yeast cells detected by direct microscopic examination of the corneal material (Liesegang and Forster 1980; Agrawal et al. 1994).

HISTOPATHOLOGICAL STUDIES

These offer certain advantages over culture, when used in the diagnosis of mycotic keratitis, since contamination is avoided, tissue penetration by fungi can be gauged, and the outcome of surgical procedures can be anticipated (Vemuganti et al. 2002). Some workers (Ishibashi et al. 1987; Rosa et al. 1994) believe that direct examination

of corneal biopsies or corneal buttons yields positive results more frequently than fungal cultures of the same specimens; others (Alexandrakis et al. 2000) believe the opposite. Corneal material for histopathology is obtained as a biopsy or button following penetrating keratoplasty. Most fungi can be satisfactorily stained and studied in tissue sections by light microscopy. Sections stained by hematoxylin and eosin demonstrate many salient details, but species of *Fusarium* or *Candida* may not be stained at all. Conversely, while fungi can be easily detected in sections of corneal tissue stained by the Gomori methenamine silver or periodic acid–Schiff stains (Vemuganti et al. 2002), little else can be visualized. Hence, a replicate tissue section stained with hematoxylin and eosin should always be examined before special stains for fungi are used; alternatively, a section stained by Gomori methenamine silver can be counterstained by hematoxylin and eosin to simultaneously demonstrate a mycotic agent and the evoked tissue response (Chandler 1991). The purulent inflammatory cellular reaction (mostly of lymphocytes and plasma cells, with variable involvement of polymorphonuclear leukocytes) is usually less intense in fungal than in bacterial keratitis; filamentous fungi are usually found deep in, and arranged parallel to, the corneal stromal lamellae, while being absent on the surface (Figure 14). Stromal abscesses arising from coagulative necrosis, 'satellite' microabscesses, focal necrosis of the corneal stroma, and clusters of acute inflammatory cells may also be seen (Agrawal et al. 1994). At this stage, healing of the epithelium is seen with a coexisting active proliferation of the fungus in the deeper stroma, which may explain why culture of corneal biopsies, where material is obtained from the depth of the stroma, yields results superior to culture of corneal scrapings (Ishibashi and Kaufman 1986b; Brooks and Coster 1993; Rosa et al. 1994; Kompa et al. 1999). Invasion and penetration of an apparently intact Descemet's membrane may occur rarely (Vemuganti et al. 2002), particularly when *Fusarium solani* or *Fusarium* spp. are the infecting organisms (Jones 1975; Kuriakose and Thomas 1991).

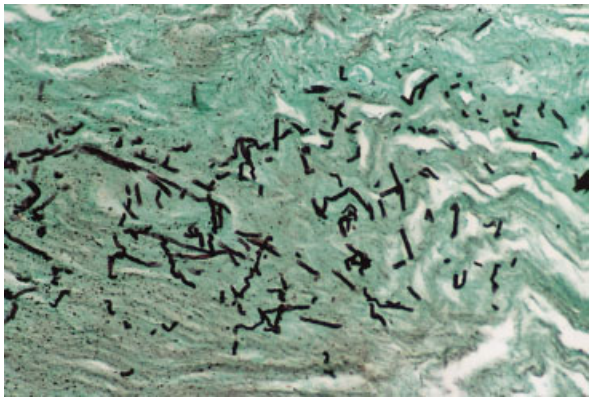

Figure 14 *Photomicrograph of a tissue section from a corneal button removed at the time of therapeutic penetrating keratoplasty. Fungal hyphae are seen in the middle and deep layers of the corneal stroma. The hyphae are oriented mostly in a direction parallel to that of the corneal collagen bundles. Gomori methenamine silver stain; magnification ×400*

Lectins, such as concanavalin A and wheat germ agglutinin, are ubiquitous proteins, found especially in plant seeds that bind specifically to carbohydrates. Fluorescein-conjugated concanavalin A provided consistently bright staining of fungal structures in corneal scrapes from 18 patients with culture-proven mycotic keratitis (Robin et al. 1989). A peroxidase-labeled wheat germ agglutinin staining technique for diagnosis of experimental keratitis due to *Candida albicans*, *Aspergillus fumigatus*, and *Fusarium solani* has recently been described (Garcia et al. 2002); this technique exhibited excellent sensitivities and specificities for all three infections, with a high degree of test–retest and inter-rater concordance between two independent observers. Such a sensitive and specific technique could prove useful in the clinical setting without the need for microscopes with attachments for fluorescence microscopy.

Fluorescence microscopy of a tissue section stained by hematoxylin and eosin revealed the presence of yeast cells of *Blastomyces dermatitidis* in periocular cutaneous lesions that had initially been misdiagnosed as squamous cell carcinoma (Margo and Bombardier 1985). Detection of fungi by direct immunofluorescence of formalin-fixed, paraffin-embedded ocular tissue sections has helped to confirm a presumptive histological diagnosis of ocular infection due to *Blastomyces dermatitidis* (Vida and Moel 1974), *Histoplasma capsulatum* var. *capsulatum* (Macher et al. 1985), *Sporothrix schenckii* (Font and Jakobiec 1976), *Pythium insidiosum* (Mendonza et al. 1996), and a zygomycete (Orgel and Cohen 1989). This technique can be used to detect a variety of dimorphic and hyaline filamentous fungi, even when these are present in small numbers or as atypical forms (Chandler 1991). Moreover, for retrospective studies, tissue sections previously stained by the hematoxylin and eosin, Giemsa, and modified Gram procedures can be decolorized in acid-alcohol and then restained with the specific reagents used for immunofluorescence (Chandler 1991). Performing immunofluorescence on a routine basis requires a microscope with attachments for fluorescence microscopy, antibodies of good quality, and standardization of the reagents and procedures used.

An impression debridement procedure has been described for corneal ulcers, although not specifically for mycotic keratitis (Arora and Singhvi 1994), where cellulose acetate filter paper (of the type used for conjunctival impression cytology) is applied with gentle pressure to the ulcerated part of the cornea; debridement is achieved with no trauma to the cornea since the necrotic material sticks to the filter paper, and this material can then be removed and stained. Degenerated epithelial and inflammatory cells and microorganisms can be seen

by microscopic examination of the necrotic material (Arora and Singhvi 1994).

Despite a clear clinical presentation of suppurative keratitis, traditional diagnostic laboratory methods, including microscopy and culture, may yield negative results in 31–50 percent of patients, possibly due to difficulties in obtaining sufficient corneal material from large, late-stage ulcers, due to the risk of perforation, and from early stage, small ulcers from which little material is available (Leck et al. 2002). Self-administration of antimicrobials by patients before seeking medical attention may compound the problem (Dunlop et al. 1994). This has led to an evaluation of the polymerase chain reaction (PCR) as an aid to the diagnosis of mycotic keratitis.

POLYMERASE CHAIN REACTION

This technique, which achieves enzymatic amplification of a specific sequence of DNA, can be used to detect the DNA of fastidious microorganisms which cannot be cultured easily or for which culture is prolonged (for example, in patients who have been on antimicrobial therapy). DNA can be extracted from minute quantities (1 μl) of intraocular fluid (aqueous or vitreous), tears, any fresh ocular tissue, formalin-fixed or paraffin-embedded tissue, and even stained or unstained cytology slides or tissue sections for analysis by the PCR (Rajeev and Biswas 1998). However, this technique can neither be used to monitor a patient's response to treatment, nor to distinguish viable from nonviable organisms. It may thus be difficult to assess the relevance of a positive PCR, especially in locations such as the conjunctival sac, where bacteria, and even fungi, may normally be found; similarly, PCR cannot differentiate between active and latent viral infection (Rajeev and Biswas 1998). A few culture media will suffice to detect and grow the common ocular pathogens, but PCR must be multiplexed for each microorganism that is suspected (the use of panfungal primers may alleviate this problem). PCR can detect only those organisms for which the DNA sequence and primers are known, and cannot provide details of cellular morphology or localization (Rajeev and Biswas 1998).

In ocular fungal infections, PCR has principally been used in the diagnosis of endophthalmitis due to *Candida* spp. (Okhravi et al. 1998; Hidalgo et al. 2000; Jaeger et al. 2000). However, this technique permitted a postmortem diagnosis of *Fusarium* panophthalmitis in one patient (Alexandrakis et al. 1996). When the PCR was applied to the diagnosis of experimental keratitis due to *Fusarium solani*, using primers directed against one part of the *Fusarium* cutinase gene, amplified target DNA sequences were noted in 89 percent of 28 samples from *Fusarium*-infected corneas, whereas only 21 percent of 14 samples from infected corneas were positive by culture. However, one of eight negative control samples was also positive by PCR (specificity of 88 percent for PCR) while none of the negative controls yielded growth in culture (100 percent specificity for culture) (Alexandrakis et al. 1998). When PCR was applied to the study of corneal scrapes from 30 patients with presumed microbial keratitis, using primers to target the 18S ribosome of fungi, PCR and culture yielded positive results for fungi in samples from 15 patients, and both techniques were negative in seven samples; however, PCR was positive for fungi with a negative culture in seven patients, while PCR was negative for fungi with a positive culture in one patient. Taking a positive fungus culture as the 'gold standard,' the PCR technique had a sensitivity of 94 percent and a specificity of 50 percent in this study (Gaudio et al. 2002). The specificity of this technique for diagnosis of mycotic keratitis requires further evaluation.

ANTIFUNGAL SUSCEPTIBILITY TESTING

Some investigators have reported that antifungal susceptibility testing aids the selection of the appropriate antifungal for successful treatment of mycotic keratitis (Jones 1975; Ishibashi et al. 1984) or orbital infections (Maskin et al. 1989; Massry et al. 1996). Unfortunately, many of these reports have not provided details of the test procedures used, nor have standardized techniques been followed. The future use of reproducible tests conforming to rigorous standards, such as the approved document (M27A) of the National Committee for Clinical Laboratory Standards (1997) for sensitivity testing of yeasts, and a standard method for susceptibility testing of filamentous fungi, especially *Aspergillus* spp., may clarify whether antifungal susceptibility testing is at all useful in guiding therapy of ophthalmic mycoses. Above all, the relationship between in vitro susceptibility data and clinical response to topical antifungal medication needs to be clarified; hitherto, no studies have been performed in this important area.

Management of mycotic keratitis

Mycotic keratitis is managed by medical or surgical means. Medical therapy consists of nonspecific measures, and the use of specific antifungal agents. Cycloplegics are used to relieve the iridocyclitis (anterior uveitis) that usually accompanies mycotic keratitis while broad-spectrum antibacterials may be needed to combat secondary bacterial infection (Rosa et al. 1994; Wong et al. 1997). Where access to specific antifungal drugs is limited, efforts have also been made to evaluate various antiseptics, such as polyhexamethylene biguanide (PHMB), chlorhexidine, and silver sulfadiazine in therapy of mycotic keratitis.

ANTISEPTICS FOR MYCOTIC KERATITIS

PHMB, which exhibits good in vitro activity against bacteria, fungi, and *Acanthamoeba*, has been used as a swimming pool disinfectant, sanitizer, and preservative in

topical ophthalmic preparations (Imayasu et al. 1992), and for treatment of *Acanthamoeba* keratitis at concentrations of 0.02–0.053 percent with no adverse effects (Duguid et al. 1997). PHMB 0.02 percent was found to significantly reduce fungal growth in a New Zealand white rabbit model of *Fusarium solani* keratitis, with 58 percent of PHMB-treated eyes exhibiting no growth compared to only 17 percent of placebo-treated eyes (Fiscella et al. 1997).

Chlorhexidine, a bisbiguanide antiseptic which inhibits microbial function by affecting the functioning of the cell membrane, therein leading to a leak of cell electrolytes, has notable bactericidal and amebicidal effects (Seal et al. 1996). When corneal isolates of fungi were tested against chlorhexidine, povidone-iodine, propamidine, PHMB, and econazole by a crude, nonstandardized in vitro method, chlorhexidine exhibited antifungal activity at high concentrations while povidone-iodine was active at all concentrations tested and econazole was the most effective of all (Martin et al. 1995–96). However, in an agar-dilution method of susceptibility testing, chlorhexidine gluconate did not exhibit notable in vitro activity against ocular isolates of *Aspergillus* and *Fusarium* even at concentrations of 64 μg/ml (P. A. Thomas, unpublished observations). In a masked, randomized study on consecutive patients with microscopy-positive (later proven to be culture-positive) mycotic keratitis, 0.2 percent chlorhexidine appeared to be more effective than 5 percent natamycin in patients who did not have prior antifungal treatment (Rehman et al. 1997). In another study on 71 patients in Bangladesh (Rehman et al. 1998), neither 0.2 percent chlorhexidine gluconate nor 2.5 percent natamycin proved effective for healing of severe ulcers at 21 days, while 66.7 percent of nonsevere ulcers treated with chlorhexidine, and 36 percent of those treated with natamycin, had healed at 21 days, a relative efficacy of 1.85 (Rehman et al. 1998). However, since only a 2.5 percent strength natamycin suspension was used, and not the conventional 5 percent concentration, the relative efficacy of chlorhexidine *vis-à-vis* natamycin was probably overestimated.

Silver sulfadiazine functions as an organic base-heavy metal release system by liberating silver. The silver component binds to microbial DNA, preventing unzipping of the helix and therein inhibiting the replication of microorganisms without interfering with epithelial cell regeneration. In a prospective, controlled, randomized, double-masked trial on therapy of mycotic keratitis (Mohan et al. 1988), a higher success rate was achieved with the use of 1 percent silver sulfadiazine ointment (80 percent), without significant ocular or systemic adverse effects, than with 1 percent miconazole ointment (55 percent); the response of *Aspergillus* keratitis was comparable in both groups but silver sulfadiazine was superior to miconazole in patients with *Fusarium* keratitis. However, these excellent results have not been corroborated by other workers.

SPECIFIC ANTIFUNGAL AGENTS

Medical therapy of mycotic keratitis is usually protracted since the effective concentrations achieved by most specific antifungal agents in the cornea, with the possible exception of amphotericin B, only inhibit growth of the fungus, and host defense mechanisms must eradicate the organism (Stern and Buttross 1991). The antifungal agents used in clinical practice can be classed as polyenes, pyrimidines, and azoles.

Polyenes

Amphotericin B exerts its antifungal effect by directly bonding to ergosterol, a sterol unique to fungal cell membranes, therein disrupting the structural integrity of the membrane (O' Brien 1999). This antifungal penetrates the deep corneal stroma after topical application, and its bioavailability is sufficient for susceptible fungi; it also exhibits immunoadjuvant properties (Johns and O'Day 1988). In a model of deep stromal infection due to *Candida albicans* in pigmented rabbits, amphotericin B 0.15 percent and 0.075 percent and natamycin 5 percent exhibited a significant antifungal effect when the cornea was debrided every day; when the epithelium was left intact, the efficacy was much reduced or negligible (O'Day et al. 1984a). In the same model, the efficacy of amphotericin B (0.15 percent and 0.5 percent) appeared unaffected when the antifungal was given with 1 percent prednisolone acetate (O'Day et al. 1984b). Amphotericin B methyl ester was also found to be very efficacious in this model (O'Day et al. 1984c). Since the initial report of Wood and Williford (1976), varying degrees of success have been reported when amphotericin B (0.15 to 0.3 percent) is used to treat clinical mycotic keratitis. Topical hourly applications of amphotericin B (0.15 percent) resulted in resolution of lesions in 56 percent of keratitis due to *Fusarium* and 27 percent of keratitis due to *Aspergillus* in Indian patients (Thomas and Rajasekaran 1988), while use of amphotericin B ointment resulted in resolution of keratitis due to *Aspergillus* spp. and *Fusarium* spp. (Hirose et al. 1997). Keratitis due to *Curvularia brachyspora* resolved with topical amphotericin B therapy alone (Marcus et al. 1992). An analysis of several reports (Wilhelmus and Robinson 1991; Rosa et al. 1994; Hemady 1995; Ainbinder et al. 1998; Lin et al. 1999; Tanure et al. 2000; Djalilian et al. 2001) reveals that 24 of 28 patients with keratitis due to *Candida albicans* and other *Candida* spp. responded to amphotericin B (15 patients to topical amphotericin B alone, one to intravenous amphotericin B alone, and eight to topical amphotericin B in combination with natamycin or systemic azoles). When collagen shields that had been soaked in 0.5 percent amphotericin B for 2 hours at 25°C before application were used in conjunction with amphotericin B 0.25 percent eye drops (applied every 2 hours), cultures from the eyes of three patients with *Aspergillus* keratitis

became negative within 15 days of treatment, although two patients subsequently required keratoplasty (Mendicute et al. 1995). Collagen shields, thus prepared and replaced daily, may deliver adequate concentrations of amphotericin B to the cornea with better tolerance than when conventional drops are used, therein improving the prognosis of *Aspergillus* keratitis. Although topical application of amphotericin B (in a desoxycholate vehicle) was found to prevent healing of epithelial defects in rabbit eyes, and to cause severe stromal edema and worsening iridocyclitis (Foster et al. 1981), the 0.15 percent solution prepared from the commercially available intravenous preparation appears to be well-tolerated (Tanure et al. 2000). Peripheral keratitis accompanying nasal rhinosporidiosis was found to resolve following topical administration of amphotericin B, prompting the suggestion that amphotericin B is an effective drug in this condition (Bhomaj et al. 2001). However, the peripheral keratitis in this patient is likely to have resolved due to the diagnostic corneal scraping that was performed, as well as the nasal polypectomy.

Natamycin (pimaricin), the first antifungal specifically developed for topical ophthalmic use, also binds to ergosterol to induce fungal cell membrane damage (O'Brien 1999). This drug is heat stable, permitting heat sterilization to be used, and the 5 percent topical ophthalmic suspension is well-tolerated, effective, and safe, although occasional punctate keratitis has been reported (Johns and O'Day 1988). Subconjunctival injection leads to conjunctival necrosis, and natamycin is not available for systemic administration due to its low aqueous solubility (O'Brien 1999). It has been suggested that natamycin does not penetrate into the deep corneal stroma after topical application. However, radiolabeling studies revealed that 13 topical applications of natamycin (one every 5 minutes) resulted in a drug concentration of approximately 2.5 mg/g of cornea, levels that were substantially higher than those following application of amphotericin B, although the levels achieved were far less in nondebrided corneas with intact epithelium (O'Day et al. 1986). About 2 percent of the total drug in the corneal tissue is bioavailable. Where commercially available, natamycin 5 percent is used as primary therapy for mycotic keratitis, particularly that due to filamentous fungi (Agrawal et al. 1994; Rosa et al. 1994; Panda et al. 1997), but interpretation of data relating to response to therapy has been difficult. In one series in Miami, Florida (Rosa et al. 1994), patients with presumably superficial keratitis due to *Fusarium* spp. received topical natamycin alone (average duration of treatment was 38 days), while those with presumably deep lesions received topical natamycin and systemic antifungals. Details of response to therapy were not provided, but 22 (28 percent) of 79 eyes with *Fusarium* keratitis ultimately required penetrating keratoplasty, and one eye required enucleation. It is uncertain whether the patients who did not require surgery ultimately responded to therapy with natamycin (with or without systemic antifungals). A recent report from the same institution (Dursun et al. 2003) provided data about 10 cases (out of a total of 159 patients with *Fusarium* keratitis) that progressed to endophthalmitis; combination therapy with oral azoles (fluconazole or ketoconazole) and topical natamycin appeared to be inadequate in severe *Fusarium* keratitis with intraocular spread. In the same center, four patients with keratitis due to *Candida* spp. were reported to have responded to topical natamycin therapy alone (Rosa et al. 1994). In a review of patients with *Curvularia* keratitis in Houston, Texas, it was noted that the corneal lesions resolved with topical natamycin therapy alone in 16 patients; in an additional seven patients, the lesions resolved following medical therapy with topical natamycin and other antifungals, and in another six patients, the keratitis resolved with topical natamycin, other antifungals, and surgery (Wilhelmus and Jones 2001). Variable results have been reported when topical natamycin has been used to treat keratitis due to *Scedosporium apiospermum* (reviewed by Wu et al. 2002).

Pyrimidines

Flucytosine (5-fluorocytosine), a low molecular weight, fluorinated cytosine analog that was first synthesized as a potential antineoplastic agent, exhibits moderate aqueous solubility, a high bioavailability, and achieves anterior chamber levels of 10–40 μg/ml after oral administration of 200 mg/kg body weight/day (Jones 1975). In spite of these advantages, flucytosine has limited use in ocular fungal infections. Since many strains of fungi have rapidly developed resistance to this drug, flucytosine should not be administered alone to treat mycotic keratitis or intraocular infections, even when these are caused by susceptible fungi (O'Brien 1999). Flucytosine also has a limited spectrum of activity against the commonest filamentous fungi implicated in ocular disease (Sutton et al. 1998). Since low intraocular levels of the drug are achieved after topical and subconjunctival administration, the use of oral doses of 50–150 mg/kg body weight/day or a topical 1 percent solution is recommended (O'Brien 1999).

Azoles

As a group, the azoles are potentially as effective as amphotericin B since they have a broad spectrum of activity, are generally less toxic, and can be administered by different routes. Since azoles bind to a cytochrome P450 fungal enzyme involved in the 14α-demethylation of either lanosterol or 25-methylene-dihydrolanosterol, ergosterol synthesis decreases and 14-methylated sterols accumulate, leading to increased membrane permeability, inhibition of growth, and alteration of membrane

enzymes, ultimately causing cell death, and also rapid accumulation of chitin over the entire cell wall (Vanden Bossche et al. 1993). All azoles, except for fluconazole, appear to decrease immune cell function, especially that of lymphocytes, thus affecting the degree of tissue damage occurring with the inflammatory reaction, but also affecting the efficacy of the azoles in vivo (Yamaguchi et al. 1993). In view of the limited concentrations of azoles that can be achieved in the eye, these drugs are to be considered as fungistatic in ocular fungal infections (Johns and O'Day 1988).

Clotrimazole is a trityl imidazole of low human toxicity with in vitro activity against species of *Aspergillus*, *Alternaria*, and *Candida*, but not against species of *Fusarium* or *Paecilomyces* (Jones 1975). Clotrimazole is poorly soluble in water, hence parenteral administration is not feasible. Following oral administration, satisfactory blood levels are reached during the first 2 weeks of therapy, but subsequently fall due to rapid induction of hepatic drug-metabolizing enzymes. Hence, clotrimazole is no longer recommended for oral administration (O'Brien 1999). Successful therapy of 16 patients with fungal keratitis (including eight due to various species of *Aspergillus*, and three due to *Candida albicans* and other *Candida* spp.) by using a commercial preparation of clotrimazole (Canesten, Bayer, Germany) was reported in 1976 (Jones et al. 1976). A topical 1 percent solution of clotrimazole in arachis oil was also found useful in therapy of superficial corneal infections (Jones et al. 1979). There are no recent reports of the use of clotrimazole in therapy of mycotic keratitis.

Econazole, a dichloroimidazole that is similar to miconazole in structure and mode of action, has a wide spectrum of activity against filamentous fungi in vitro, but is less effective than miconazole against *Candida* spp. These data may explain why econazole was found effective in treatment of keratitis due to various fungi, including species of *Fusarium* (Jones 1975; Jones et al. 1979; Arora et al. 1983). However, topical administration of a 1 percent econazole solution in polyethylene glycol 400 was not efficacious in experimental deep stromal *Candida albicans* keratitis in pigmented rabbits (O'Day et al. 1984a), irrespective of whether the corneal epithelium was intact or debrided. A recent study in India suggested that 2 percent econazole was as effective as 5 percent natamycin in therapy of filamentous fungal keratitis (Prajna et al. 2003); however, the results were not stratified as to severity of keratitis or the fungus involved.

Miconazole, a phenylethyl imidazole which exhibits a broad spectrum of activity against yeasts and filamentous fungi, is soluble in organic solvents, and may be administered intravenously in normal saline after dissolving in cremophor EL; this vehicle is believed to cause the toxic reactions observed with intravenous miconazole administration (Anderson et al. 1984). Following subconjunctival and topical administration, miconazole was found to penetrate the corneas of rabbit eyes, resulting in high tissue concentrations that were enhanced by epithelial debridement (Foster and Stefanyszyn 1979). In a rabbit model, topical 1 percent miconazole nitrate did not retard the closure of 8.5 mm corneal epithelial defects (Foster et al. 1981). Topical administration of 1 percent miconazole nitrate in polyethylene glycol 400 was not effective in a rabbit model of deep stromal *Candida albicans* keratitis (O'Day et al. 1984a), irrespective of whether the corneal epithelium was intact or debrided. In another study (O'Day et al. 1984b) topical 1 percent prednisolone acetate was found to adversely influence the efficacy of 1 percent miconazole and other antifungals when given in combination (O'Day et al. 1984b). Although intravenous administration of miconazole resulted in undetectable drug concentrations in the cornea and vitreous of rabbit eyes (Foster and Stefanyszyn 1979), intravenous administration in a dose of 600–3 600 mg/day was reported to be effective in the treatment of clinical mycotic keratitis due to *Phialophora gougerotii* (Jones 1975), *Lasiodiplodia theobromae* (Ishibashi and Matsumoto 1984b), *Beauveria bassiana* and *Aspergillus fumigatus* (Ishibashi et al. 1984). Topical and subconjunctival miconazole therapy (Foster 1981) resulted in resolution of all lesions, including endothelial plaques and a descemetocele, in seven patients with keratitis due to *Candida albicans* or *Aspergillus* species; all seven fungal strains were reportedly susceptible in vitro to miconazole. Topical (1 percent) and subconjunctival miconazole therapy, combined with oral ketoconazole, evoked a favorable response in 13 of 20 patients with keratitis due to species of *Fusarium*, *Curvularia*, or *Candida*; a modification of the regimen produced healing in three more patients, while the lesions progressed in four patients (Fitzsimons and Peters 1986). Since many strains of *Scedosporium apiospermum* (*Pseudallescheria boydii*) are reported to be susceptible to miconazole in vitro (Sutton et al. 1998), miconazole is believed to be an important drug in treatment of clinical keratitis due to this fungus. A recent review of 15 patients with this condition (Wu et al. 2002) appears to endorse this view (only reports where details of treatment regimen and visual outcome were provided were included in the review, and patients with initial scleral involvement were excluded). Four (67 percent) of six individuals who had received miconazole and three (33 percent) of nine persons who had not received miconazole retained form vision (counting fingers or better). It is important to remember that the severity of the keratitis at presentation could be an important determinant of outcome of medical therapy. Topical miconazole therapy is sometimes associated with superficial punctate keratitis which resolves when treatment is withdrawn (Foster 1981).

Ketoconazole, the first successful orally absorbable, broad-spectrum antifungal azole, is a substituted imidazole compound that is currently available as an oral preparation (200 mg) worldwide and as a 1 percent topical ocular medication in India. Following subconjunctival, topical, or oral administration of a 1 percent ketoconazole solution to rabbits with undebrided corneas and an intact epithelium, relatively high concentrations of ketoconazole were achieved in the cornea (44.0±10.1 μg/g) but relatively nondetectable levels in the vitreous; greatly increased corneal drug levels (1 391.5±130.0 μg/g) were achieved, particularly after topical administration and, to a lesser extent, after subconjunctival injection, after debridement of the corneal epithelium (Hemady et al. 1992). Following systemic administration, ketoconazole is highly bound to serum protein, but also has a high tissue distribution (O'Brien 1999). Transscleral iontophoresis (4–6 mA for 15 minutes) resulted in peak ketoconazole concentrations of 10.2 μg/ml in the aqueous after 1 hour (which persisted for about 8 hours) and 0.1 μg/ml in the vitreous; transcorneal iontophoresis (1.5 mA for 15 minutes) resulted in peak corneal concentrations (27.6 μg/ml) and aqueous concentrations (1.4 μg/ml) after 1 hour, which were sustained for 2 hours. These concentrations were significantly higher than those achieved by subconjunctival injections (Grossman and Lee 1989).

Oral doses of ketoconazole greater than 400 mg/day may cause nausea, vomiting, and transient elevations in liver enzymes, which resolve upon withdrawal of the drug; sexual impotence, hair loss, gynecomastia, and oligozoospermia may also occur, due to decreased steroid synthesis (O'Brien 1999). While a 1 percent ketoconazole suspension (prepared in polyethoxylated castor oil) was reported to produce modest pathological changes in the regenerating corneal epithelium in a rabbit model (Foster et al. 1981), topical administration of 1 percent, 2 percent, and 5 percent solutions of ketoconazole in arachis oil did not cause corneal toxicity in rabbit eyes (Oji 1982b). When a topical 2 percent ketoconazole suspension (prepared in a 4.5 percent sterile boric acid solution with hydroxypropylmethyl cellulose added to increase viscosity) was used to treat clinical mycotic keratitis, it did not evoke significant ocular toxicity (Torres et al. 1985).

The results of experimental studies suggest that the response of ocular fungal infections to ketoconazole is species-specific. Topical 1 percent ketoconazole (in arachis oil) applied every hour for 10 hours for 16 days was effective in clearing *Aspergillus flavus* keratitis in a rabbit model (Oji 1982a) whereas oral or topical ketoconazole therapy was not successful in experimental *Aspergillus fumigatus* keratitis (Komadina et al. 1985). Topical 1 percent ketoconazole solution was ineffective in one experimental model of *Candida albicans* keratitis (O'Day et al. 1983), but topical 2 percent ketoconazole ointment was effective in another model (Ishibashi and Kaufman 1986a). Oral ketoconazole therapy was also effective in experimental *Candida albicans* keratitis (Ishibashi and Matsumoto 1984a).

In a clinical setting, oral ketoconazole therapy was not found effective in one patient with *Aspergillus fumigatus* keratitis, perhaps because of intraocular invasion (Searl et al. 1981), but was effective in a dose of 300 mg/day in two patients with mycotic keratitis, one due to *Fusarium solani* (therapy for 3 weeks), and the other due to an unidentified fungus (therapy for 8 weeks) (Ishibashi 1983). Topical 1 percent ketoconazole, given for 7 weeks, was reported to be effective in the treatment of six patients with mycotic keratitis, principally caused by *Aspergillus* and *Fusarium* (Torres et al. 1985). In these reports, the efficacy of ketoconazole therapy in severe mycotic keratitis caused by different fungi could not be assessed. When 30 patients suffering from mycotic keratitis were treated with oral ketoconazole (200 mg three times per day), there was complete resolution of lesions in all 14 patients with superficial lesions, and six of 16 patients who had deep lesions; none of the patients reported adverse effects to the drug, nor were marked elevations in serum enzyme levels observed (Thomas et al. 1987). In an extension of this study, 10 of 15 patients treated only with a topical 1 percent ketoconazole suspension in distilled water responded, while in 25 of 35 patients treated with topical and oral therapy, a complete or partial response of the keratitis was noted (Rajasekaran et al. 1987a). A comprehensive assessment of the data from both studies indicates that oral therapy alone was effective in 37 percent of patients with deep lesions, topical therapy alone was effective in 20 percent, and combined oral and topical therapy effected complete or partial resolution of the keratitis in 60 percent of patients, including 10 of 30 patients with *Fusarium* keratitis, 11 of 22 patients with *Aspergillus* keratitis, three of five patients with *Penicillium* keratitis, three of four patients with *Candida albicans* keratitis and in all six patients with *Curvularia* keratitis (Rajasekaran et al. 1987a; Thomas et al. 1987). A combination of ketoconazole and amphotericin B therapy and keratoplasty resulted in a favorable outcome of post-traumatic keratitis due to *Scopulariopsis brevicaulis* in a patient (Ragge et al. 1990), whereas treatment with oral ketoconazole could not halt progressive infection due to the thermotolerant mold *Neosartorya fischeri* var. *fischeri*, the teleomorph of *Aspergillus fischerianus* (Coriglione et al. 1990). In south Florida, 25 of 125 patients with mycotic keratitis, seen over a 10-year period, received oral ketoconazole (400 mg/day for a median duration of 2 weeks), in addition to topical 5 percent natamycin, due to severe keratitis, scleritis, and endophthalmitis; nine (36 percent) of these 25 patients did not require a therapeutic penetrating keratoplasty or other major surgical

intervention to manage their keratitis (Rosa et al. 1994). All these results suggest that while oral ketoconazole therapy is undoubtedly efficacious in nonsevere mycotic keratitis, its efficacy when deep lesions are present is variable, and also depends on the fungal species involved.

Whether the results of oral ketoconazole therapy for mycotic keratitis have any relevance at all to topical therapy is debatable. Triturated (crushed and suspended) ketoconazole has been recommended for the treatment of mycotic keratitis when commercial antifungal eye drops are not obtainable (Guzek et al. 1998). Ketoconazole and itraconazole tablets were triturated to 20 mg/ml in polyvinyl alcohol, boric acid, olive oil, or balanced salt solution (BSS) and applied topically to de-epithelialized rabbit corneas (one drop/15 minutes for 2 hours). The concentrations of ketoconazole in corneal tissue treated with the drug in BSS, olive oil, polyvinyl alcohol, and boric acid were calculated to be 512, 773, 1 221, and 1 492 μg/g, respectively. Since the vehicle used to triturate antifungals may affect the tissue concentration, the development of effective vehicles may have an impact on the therapy of mycotic keratitis.

Itraconazole, an orally absorbable synthetic dioxolane triazole with a broad spectrum of antifungal activity after oral administration, is larger than fluconazole, very hydrophobic, and poorly soluble in aqueous solution. It is well absorbed orally, especially when given with a meal or formulated in polyethylene glycol, with more than 90 percent being bound to protein in serum, and it is highly concentrated in lipid-rich tissue (Van Cauteren et al. 1987). Although a single 200 mg oral dose results in a peak serum level of about 0.3 μg/ml, which is far below that of ketoconazole or fluconazole (Van Cauteren et al. 1987), the serum level can be increased to 3.5 μg/ml by multiple long-term dosing (200 mg/day orally for 2 weeks) (Carlson et al. 1992). The major drawback of using itraconazole by the oral route for therapy of ocular fungal infections is its poor penetration into the cornea, aqueous humor, and vitreous, when compared to fluconazole and ketoconazole. This was clearly demonstrated in a rabbit model of *Candida* endophthalmitis, even when itraconazole was given in a dose of 80 mg/kg orally (Savani et al. 1987). The ocular pharmacokinetics of a newly developed itraconazole oral solution need to be defined (Harrousseau et al. 2000). Itraconazole is generally well-tolerated after oral administration, the most common complaint being gastrointestinal upset; less frequently observed side effects include hypertriglyceridemia, hypokalemia, edema, decreased libido, and gynecomastia (O'Brien 1999).

Oral itraconazole therapy was found to be effective in the therapy of experimental keratitis due to *Aspergillus* spp. (Van Cutsem and van Gerven 1991). In India (Thomas et al. 1988), 22 of 40 patients with mycotic keratitis (15 with nonsevere and seven with severe keratitis) responded to oral itraconazole (200 mg once daily for a median duration of 17 days); serious adverse reactions did not occur, and all hematological, urine, and biochemical parameters remained normal during and after itraconazole therapy. In a related study (Rajasekaran et al. 1987b), seven of eight nonsevere ulcers and one of eight severe ulcers healed with topical therapy alone, while 17 of 21 nonsevere ulcers and 14 of 33 severe ulcers responded to a combination of oral itraconazole (200 mg once daily) with hourly topical applications of 1 percent itraconazole. To summarize these data, 84 percent of nonsevere ulcers and 57 percent of severe ulcers showed excellent or moderate responses to some form of itraconazole therapy; 76 percent of patients with *Aspergillus* keratitis, 70 percent of those with dematiaceous filamentous fungal keratitis, and 60 percent of patients with *Fusarium* keratitis exhibited excellent or moderate responses to some form of itraconazole therapy (Rajasekaran et al. 1987b; Thomas et al. 1988). In another study, a recurring corneal infection due to *Fonsecaea pedrosoi* was treated by a large penetrating keratoplasty, removal of the involved part of the iris and the entire lens, and a 5-month course of oral itraconazole; this resulted in no recurrence of the infection (Barton et al. 1997).

Bioassay of corneas treated with itraconazole in different vehicles (BSS, polyvinyl alcohol, boric acid, olive oil) demonstrated approximate itraconazole concentrations of 200–250 μg/g tissue (Guzek et al. 1998). Another avenue to pursue is the possible use of itraconazole subconjunctivally. In a novel method for the qualitative evaluation of the pharmacokinetics of subconjunctivally injected antifungals in rabbits, itraconazole (2.5 mg/ml) was found to persist for at least 24 hours in normal and debrided corneas, in contrast to amphotericin B, miconazole, fluconazole, and ketoconazole, which did not persist beyond 4–8 hours (Klippenstein et al. 1993).

Fluconazole, a synthetic bistriazole antifungal compound, is a smaller molecule than itraconazole, soluble in water, and only 10–20 percent protein bound in serum; it has a long half-life and is excreted renally (Savani et al. 1987). In one study (O'Day et al. 1990), oral fluconazole was found to readily penetrate all ocular tissues and fluids of Dutch-belted rabbits, with no difference observed between phakic and aphakic eyes; after a single oral dose of 20 mg/kg, the levels achieved were 13.3±1.4 μg/g (cornea), 7.4±0.3 mg/l (aqueous), 9.8±0.9 mg/l (vitreous), and 5.2±0.4 μg/g (choroid/retina), with the corneal concentrations being highly correlated with serum concentrations. A steady accumulation in both normal corneas, as well as those infected with *Candida albicans*, was noted when given in a twice-daily divided dose; the presence of inflammation induced by fungal infection did not influence corneal uptake (O'Day et al. 1990). In a related experimental study in

Dutch-belted rabbits (O'Day 1990), oral fluconazole therapy resulted in a significant therapeutic effect in keratitis due to *Aspergillus fumigatus* keratitis and that due to *Candida albicans*; pretreatment for 1 day followed by 5 days post-inoculation treatment, led to a significant decrease in isolate recovery and in clinical disease.

Since fluconazole is a stable, water-soluble, low molecular weight bistriazole with high bioavailability and low toxicity, it is potentially useful as a topical ocular agent. In New Zealand white rabbits, topical application of 0.2 percent fluconazole to debrided and nondebrided corneas resulted in peak corneal levels of 8.2±1.2 μg/g (debrided corneas) and 1.6±0.6 μg/g (nondebrided) being noted after 5 minutes, and aqueous humor levels of 9.4±2.3 μg/ml and 1.6±0.6 μg/ml after 15 minutes; the half-life of fluconazole in debrided eyes was 15 minutes and that in nondebrided eyes was 30 minutes (Yee et al. 1997).

In experimental *Candida albicans* keratitis, topical (2 mg/ml) fluconazole, applied to debrided and nondebrided corneas of rabbits, was significantly better than control saline therapy in effecting clinical resolution of corneal lesions and hypopyon, nonprogression to corneal perforation and descemetocele, and eradication of the infecting fungus from the cornea (Behrens-Baumann et al. 1990). In a clinical setting, six consecutive eyes of patients with microbiologically proven *Candida* keratitis with abscess formation, which had failed to respond to topical miconazole or natamycin therapy, responded well to topical fluconazole (20 mg/ml) given for a mean duration of treatment of 22.6±2.3 days (Panda et al. 1996), while oral fluconazole therapy was reported to be useful in therapy of keratitis due to an unspecified fungus (Thakar 1994), and, in association with topical natamycin and intracameral amphotericin B and various surgical measures, to effect the eradication of corneal infection due to *Colletotrichum graminicola* (Ritterband et al. 1997). Although *Candida guilliermondii* is usually susceptible to fluconazole in vitro (Sutton et al. 1998), infectious crystalline keratopathy due to this yeast in a corneal transplant progressed, in spite of 6 weeks of topical amphotericin B, and an additional 6-week course of topical and oral fluconazole (Ainbinder et al. 1998).

SELECTION OF ANTIFUNGAL THERAPY

The selection of an antifungal agent for therapy necessarily depends on its easy availability and on other criteria. If direct microscopic examination of corneal scrapes or corneal biopsies yields definite results that are consistent with the clinical picture, treatment may be initiated; otherwise, therapy may need to be withheld until culture reports become available (Johns and O'Day 1988). Topical natamycin (5 percent), if commercially available, or amphotericin B (0.15 percent) is usually selected as first-line therapy for superficial keratitis (topical econazole is used in many parts of the UK) whether or not septate hyphae or yeast cells have been seen by direct microscopy; if deep lesions are present, intravenous amphotericin B, subconjunctival or intravenous miconazole, oral ketoconazole, oral itraconazole or oral fluconazole is added to the therapeutic regimen (Rosa et al. 1994; Wong et al. 1997; Tanure et al. 2000). If hyphae have been seen by microscopy, and a filamentous fungus is isolated in culture, natamycin appears to be the treatment of choice when available (Rosa et al. 1994; Tanure et al. 2000); topical 0.15 percent amphotericin B (Johns and O'Day 1988; Wong et al. 1997) is an alternative. If yeasts or pseudohyphae are seen by microscopy, and species of *Candida* or *Cryptococcus* are isolated in culture, topical 0.15 percent amphotericin B appears to be preferred when available (Rosa et al. 1994; Tanure et al. 2000), although natamycin (Rosa et al. 1994; Panda et al. 1996) and topical (1 percent) miconazole (Foster 1981; Panda et al. 1996) are the choices of some other clinicians. In the absence of controlled clinical trials and since the number of patients involved may be very small, the validity of these patterns of prescribing is difficult to assess. However, it may be possible to discern patterns by a detailed analysis of the available literature.

Thomas (2003) performed an analysis of 85 patients with keratitis due to *Fusarium* spp. reported in 15 studies in the literature where details of outcome of therapy were provided. The analysis revealed that more than 70 percent of patients with superficial keratitis due to *Fusarium solani* and other *Fusarium* spp. apparently responded to medical therapy alone (topical amphotericin B alone or in combination with topical natamycin, oral ketoconazole and/or topical ketoconazole, oral itraconazole); although several antifungals were found effective, administration of natamycin may have forestalled surgical intervention. In striking contrast, almost 70 percent of patients with *Fusarium* keratitis with deep lesions did not respond to medical therapy alone, particularly if natamycin was not used, and some form of surgical intervention was necessary. The data pertaining to outcome of therapy was analyzed (Thomas 2003) for 61 patients with *Aspergillus* keratitis (Figure 15) reported in 13 studies in the literature. The data suggested that more than 80 percent of patients with superficial keratitis due to *Aspergillus flavus*, *Aspergillus fumigatus*, and other *Aspergillus* spp. responded to medical therapy with a variety of topical (amphotericin B, natamycin, ketoconazole, itraconazole) or systemic (oral ketoconazole, oral itraconazole) antifungals, with surgery not being required; however, in the presence of deep corneal lesions, almost 60 percent of patients did not respond to medical therapy alone, particularly if natamycin was not used, and surgery was required to control the infection.

Details of reponse of keratitis due to *Candida* spp. to therapy were analyzed (Thomas 2003) for 38 patients reported in eight studies. The medical therapy of kera-

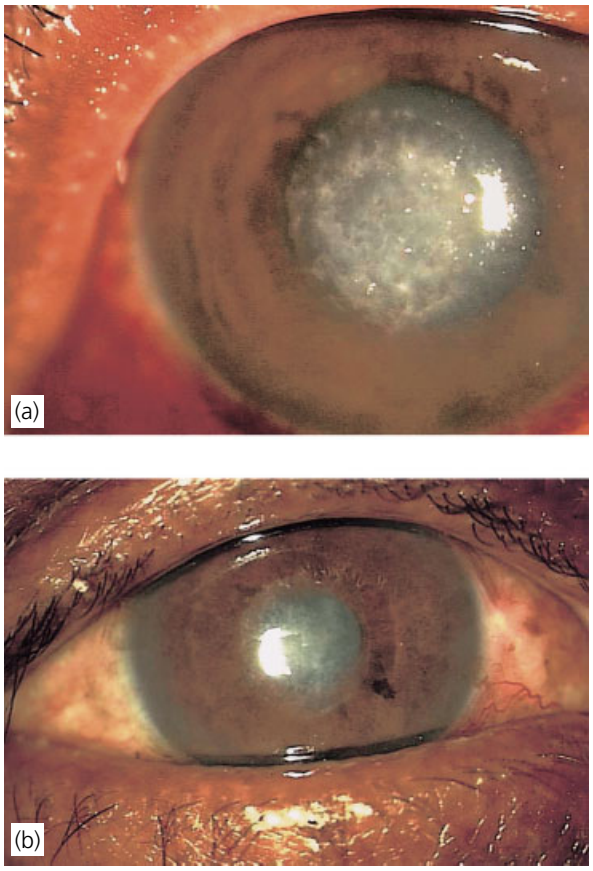

Figure 15 (a) *Keratitis due to* Aspergillus flavus *before treatment.* **(b)** *Keratitis due to* Aspergillus flavus*, 1 month after treatment with topical 5 percent natamycin. Lesions have resolved, leaving a faint scar.*

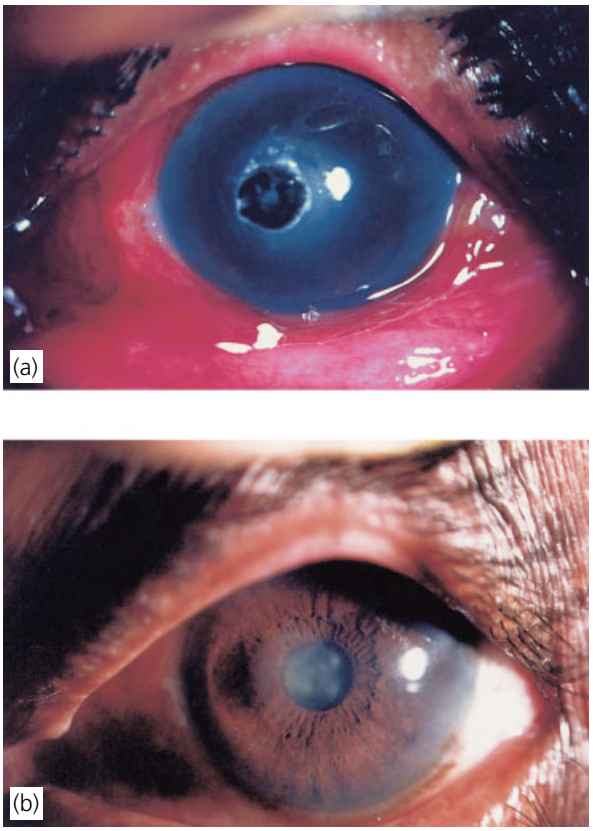

Figure 16 (a) *Keratitis due to a* Curvularia *sp. before treatment.* **(b)** *Keratitis due to a* Curvularia *sp. 1 month after treatment with topical 5 percent natamycin. Lesions have resolved, leaving a faint scar.*

titis due to *Candida albicans* and other *Candida* spp. generally had a favorable prognosis, particularly when topical amphotericin B was used alone or in combination with systemic azoles; topical natamycin and topical fluconazole alone also sufficed in some instances, and the presence of deep lesions appeared not to be a major hurdle.

Data pertaining to 42 patients with keratitis due to *Curvularia* spp. (Figure 16) reported in seven studies in the literature were analyzed (Thomas 2003). In 35 (83 percent) of the 42 individuals, the corneal lesions responded to antifungals alone (19 to topical natamycin alone, eight to natamycin and other antifungals, six to oral ketoconazole, and one each to topical miconazole and topical amphotericin B). In an additional three patients, the keratitis resolved with keratectomy and antifungal therapy, while penetrating keratoplasty was required in four patients who did not respond to medical therapy alone. Most of the papers analyzed, however, did not provide details about the severity of the corneal lesions in the patients, which is an important aspect that requires consideration. In one study on dematiaceous fungal keratitis (Garg et al. 2000), antifungal therapy alone (principally natamycin, alone or in combination with topical azoles) sufficed for resolution of lesions in 88 percent of patients with superficial lesions; however, only 46 percent of patients with deep keratitis responded to antifungal therapy alone (topical antifungals combined with oral ketoconazole), and surgery was required for the other patients. Keratitis due to dematiaceous fungi other than *Curvularia* spp. appears to respond to primary therapy with topical natamycin, oral and/or topical ketoconazole, oral ketoconazole with topical miconazole, topical amphotericin B or oral itraconazole (Thomas et al. 1987, 1988; Rosa et al. 1994; Wong et al. 1997; Garg et al. 2000). However, therapy of keratitis due to *Lasiodiplodia theobromae* is often difficult. A successful outcome of this type of dematiaceous fungal keratitis was reported in patients receiving natamycin ointment and topical or subconjunctival amphotericin B (Rebell and Forster 1976). Intravenous miconazole was also reported to be useful, but this was based on the study of a single patient (Ishibashi and Matsumoto 1984b). Poor results have been reported in patients receiving azoles (Thomas et al. 1991a, 1998; Borderie et al. 1997).

The outcome of therapy of keratitis due to *Scedosporium apiospermum* is varied. A review of 13 cases reported up to 1979 revealed a generally poor outcome,

with six of the cases eventually requiring enucleation or evisceration (Zapater and Albesi 1979). At least 14 patients with keratitis due to *Scedosporium apiospermum* have been reported in the literature since 1991 (reviewed by Wu et al. 2002). An analysis of the data pertaining to these patients (Thomas 2003) revealed that medical therapy alone sufficed for resolution of lesions in eight (57 percent) of these 14 patients (three of the 'responders' had keratitis with deep lesions), penetrating keratoplasty was needed in three patients (all had deep keratitis), and evisceration or enucleation was needed for three patients (two of whom had deep corneal lesions). Eight patients (five with deep keratitis and three with keratitis of undetermined severity) received natamycin at some time; corneal lesions resolved with medical therapy alone in three, while penetrating keratoplasty was required in the eyes of three patients, and enucleation had to be done for two patients. Six individuals (two with superficial keratitis, three with deep keratitis and one with keratitis of unknown severity) received miconazole; four resolved with medical therapy alone (two had superficial keratitis), while evisceration/enucleation was needed for two eyes (both with deep keratitis). These data suggest that, currently, keratitis due to *Scedosporium apiospermum* more frequently has a favorable outcome than that reported in the past, with evisceration or enucleation being the final result in 21 percent (compared to 54 percent in patients reported up to 1979). However, if severe keratitis is present, penetrating keratoplasty is required in addition to medical therapy. It is difficult to assess the relative efficacy of miconazole versus natamycin in view of the small numbers of patients involved.

A combination of topical antifungal therapy and keratoplasty appears to provide the most adequate treatment for keratitis due to *Acremonium* spp. (Fincher et al. 1991). A prospective evaluation of the comparative safety and efficacy of topical natamycin and 0.2 percent fluconazole was made in eight patients with filamentous fungal keratitis, including five due to *Acremonium* spp. and two due to *Curvularia* spp. (Rao et al. 1997). Corneal lesions resolved in three of four patients receiving primary natamycin treatment for a mean duration of 20 days (the keratitis worsened in the fourth patient) whereas corneal lesions failed to resolve in all four patients who received topical fluconazole as primary treatment (two subsequently responded to natamycin therapy). This study is important in providing evidence of the efficacy of topical natamycin, and the relative inefficacy of topical fluconazole, in therapy of keratitis due to filamentous fungi.

A common problem reported by all those who have had to treat keratitis due to *Pythium insidiosum* is that it is not sensitive to any of the currently available antifungals; wide surgical excision including penetrating keratoplasty has been advised for such patients, with enucleation or evisceration being required in patients who fail to respond to these measures (Virgile et al. 1993; Imwidthaya 1995; Thianprasit et al. 1996).

Fungal keratitis usually responds slowly over a period of weeks to antifungal therapy. Clinical signs of improvement of a fungal corneal ulcer include:

- diminution of pain
- decrease in size of infiltrate
- disappearance of satellite lesions
- rounding out of the feathery margins of the ulcer
- hyperplastic masses or fibrous sheets in the region of healing fungal lesions (Jones 1975; Johns and O'Day 1988).

Conjunctival chemosis and injection and punctate epithelial keratopathy may indicate toxicity of the antifungal agent being used. Negative scrapings during treatment do not always indicate that the fungus has been eradicated since it may have become deep-seated; hence therapy should be maintained for at least six weeks (Johns and O'Day 1988).

Although a combination of natamycin and ketoconazole was found to be beneficial in an animal model of *Aspergillus fumigatus* keratitis (Komadina et al. 1985), there are believed to be risks of antagonistic effects developing by the combination of certain antifungals such as amphotericin B and miconazole (Johns and O'Day 1988). Thus, methods to enhance the efficacy of existing antifungal agents require careful study.

MEASURES TO SUPPRESS CORNEAL DAMAGE DUE TO MICROBE- OR HOST TISSUE-DERIVED FACTORS

The inflammatory reaction directed against an infecting microorganism may sometimes be so severe as to damage adjacent tissues. To reduce these effects, therapy with corticosteroids and specific antimicrobials has sometimes been contemplated, since this regimen has proven satisfactory in disciform keratitis and central stromal keratitis due to the herpes simplex virus (O'Day 1991). In a recent study, Schreiber et al. (2003) tried to determine the most efficient time point and concentration of topical corticosteroids in *Candida albicans* keratitis treated with fluconazole. Their results suggested that fluconazole plus adjunctive high-dose prednisolone treatment was most effective when administered 9 days after infection. These workers concluded that the delayed application of corticosteroids after treatment with antifungals in patients with mycotic keratitis need not be a contraindication and, in fact, could be beneficial in some instances. However, most available evidence appears to weigh against the use of corticosteroids in the therapy of mycotic keratitis. In an experimental model of keratitis due to *Candida albicans*, the use of a topical corticosteroid was found to reverse the therapeutic effect of all the topical antifungals used, except for amphotericin B (0.5 or 0.15 percent) and to permit a greater replication of organisms, in comparison to

untreated controls (O'Day et al. 1984b). Moreover, corticosteroids appear to be necessary to create experimental models of mycotic keratitis (Ishibashi and Kaufman 1986a; O'Day et al. 1991), and have been found to worsen the course of existing, but unrecognized, fungal infection in the cornea (Stern and Buttross 1991; Rosa et al. 1994). This may explain why currently, the use of corticosteroids is definitely contraindicated when a specific microbicidal therapy is not used concurrently, and especially when a fungal pathogen is present. Possible 'inflammatory rebound,' a potentially devastating complication that occurs when corticosteroid therapy is abruptly terminated, also needs to considered, since this could be confused with a worsening of infection (O'Day 1991).

Since corticosteroids cannot be used to decrease the unwanted side effects of the inflammatory response in mycotic keratitis, other molecules are being evaluated. In an animal model of keratitis due to *Candida albicans*, ketorolac (a nonsteroidal anti-inflammatory compound) was found to satisfactorily reduce the tissue necrosis occurring as a result of inflammatory mechanisms, without, however, permitting progression of the infection (Fraser-Smith and Matthews 1987); there do not appear to be published reports regarding the use of this compound in clinical mycotic keratitis. A variety of mechanisms have been found to contribute to corneal damage in sterile (nonmicrobial) corneal ulceration, including:

- activation of corneal collagenase, infiltration by polymorphonuclear leukocytes, and release of free radicals in keratitis due to alkali burns (Burns et al. 1990; Alio et al. 1993, 1995)
- release of lipid mediators (Tjebbes et al. 1993)
- activation of platelet-activating factor (Tao et al. 1995).

Whether such mechanisms are relevant in pathogenesis of mycotic keratitis requires further study.

Therapeutic surgery

In the management of mycotic keratitis, surgery may be indicated in those patients who respond poorly, or not at all, to medical therapy, or where perforation or descemetocele formation is likely to occur. Prior to surgery, medical therapy should be administered for as long as possible to render the infecting fungus nonviable and therein to improve the outcome of surgery. The modalities of surgical management include removal of the corneal epithelium and anterior lamellar keratectomy, conjunctival flaps, tissue adhesives, and penetrating keratoplasty. These techniques aid medical therapy by removing infected corneal tissue (therein reducing or eliminating the microbial load) and increasing drug penetration, by bringing in blood vessels (when conjunctival flaps are formed), by stabilizing the corneal epithelial surface itself or by providing tectonic support to the entire globe when its integrity is threatened by thinning or perforation of the cornea (Agrawal et al. 1994).

In mycotic keratitis, regular debridement of the base of the ulcer helps in elimination of fungi and necrotic material and also facilitates penetration of antifungal drugs such as amphotericin B 0.15 percent and 0.075 percent and natamycin into the corneal stroma (O'Day et al. 1984c). Debridement is usually performed, under topical anesthesia, with a Bard-Parker blade no. 15, ensuring that a margin of 1–2 mm is left at the limbus (Agrawal et al. 1994). Debridement of necrotic material may suffice to induce resolution of dematiaceous fungal keratitis. The procedure of anterior lamellar keratectomy helps to remove the thick mat of fungal filaments on the cornea, therein facilitating increased drug penetration and resolution of the corneal lesions in patients with dematiaceous fungal keratitis (Jones 1975; Garg et al. 2000). Anterior (superficial) stromal corneal infiltrates can also be ablated by the excimer laser for therapeutic purposes. In an experimental model of corneal infection due to a *Fusarium* spp., photoablation by the 193 nm excimer was found useful to eradicate early, localized microbial infections, but advanced infections, with deep stromal involvement and suppuration, could not be eradicated by this technique (Gottsch et al. 1991).

Conjunctival flaps help in achieving a stable conjunctival surface in cases of persistent or recurrent epithelial defects and progressive ulceration; such flaps are especially helpful in chronic peripheral disease, where the flap does not encroach onto the visual axis (Portnoy et al. 1989; Agrawal et al. 1994). Blood vessels present in the flap brought in to cover the ulcerated area help in healing of peripheral fungal corneal ulcers; a superficial lamellar keratectomy should first be done to remove the necrotic stroma, and then a thin conjunctival flap should be anchored over the ulcerated site (Alino et al. 1998). There have been no studies evaluating the specific use of conjunctival flaps in central fungal corneal ulcers.

Permanent or temporary amniotic membrane transplantation may be a useful adjunctive surgical procedure for the management of microbial (including mycotic) keratitis by promoting wound healing and reducing inflammation (Kim et al. 2001). However, a larger number of patients needs to be studied to confirm its use in mycotic keratitis. It is also not clear whether this technique will be useful in patients who have extensive corneal epithelial ulceration and stromal infiltration, and whether the infecting fungus is completely eradicated in this procedure, or whether foci of viable fungi persist in the corneal tissue.

Tissue adhesives (cyanoacrylate 'glue') provide support to a thinned-out cornea, can seal a corneal perforation that is 2 mm or less in size (Forster 1994), and are also bacteriostatic for gram-positive bacteria

(Agrawal et al. 1994). Necrotic stromal and epithelial debris is first removed from the base of the ulcer, following which the adhesive is applied and a bandage contact lens fitted. The adhesive is left in place until it loosens spontaneously, or the bed becomes vascularized, or keratoplasty is performed.

Although penetrating keratoplasty appears to be rarely required for the treatment of active bacterial keratitis, probably due to the availability of specific antibacterial drugs, it may be required in about 15.3–27 percent of cases with mycotic keratitis (Rosa et al. 1994; Garg et al. 2000), particularly when the keratitis is caused by species of *Aspergillus* (Rosa et al. 1994; Vemuganti et al. 2002), *Fusarium* (Vemuganti et al. 2002), *Lasiodiplodia theobromae* (Borderie et al. 1997; Thomas et al. 1998), *Pythium insidiosum* (Imwidthaya 1994), and *Paecilomyces lilacinus* (Gordon and Norton 1985; Okhravi et al. 1997). Mycotic keratitis is reported to be associated with a five- to sixfold higher risk of subsequent perforation and need for penetrating keratoplasty than bacterial keratitis (Wong et al. 1997). The outcome of penetrating keratoplasty (Figure 17) also depends on whether the surgery has been performed for a bacterial or fungal corneal ulcer. In one study (Cristol et al. 1996), it was found that the graft tended to opacify much earlier in mycotic keratitis (median duration 4.0 weeks) than in bacterial keratitis (median duration 12.9 weeks). Similarly, the reported success rate for grafts in mycotic keratitis (20–60 percent) appears to be much lower than that in bacterial keratitis (70–75 percent) (Panda et al. 1991; Killingsworth et al. 1993). In one study, 25 percent of grafts performed for mycotic keratitis showed reinfection (Rosa et al. 1994). To decrease the incidence of recurrence, at least 0.5 mm of clear tissue all around the infected area should be excised. Although antifungal therapy should be continued postoperatively, topical corticosteroids should be used with caution (Stern and Buttross 1991). When donor grafts 8 mm or less in diameter were used for penetrating keratoplasty in fungal corneal ulcers, the outcome was better than when larger grafts were used (Killingsworth et al. 1993). Topical cyclosporin A (5 mg/ml) was reported to be useful as a primary or an adjunctive therapy for prevention of allograft rejection in a small number of patients with culture-proven mycotic keratitis (Perry et al. 2002).

In a recently published review of the results obtained in 45 patients with severe mycotic keratitis, in whom therapeutic penetrating keratoplasty was performed using cryopreserved donor corneas, with additional measures being irrigation of the anterior chamber with fluconazole (2 mg/ml), dissection of fibrinoid membrane on the iris and iridectomy, it was noted that the fungal infection was eradicated, and the anatomic integrity was maintained, in 39 eyes (Yao et al. 2003). Thus, cryopreserved donor corneas may be effective substitutes in therapeutic penetrating keratoplasty in severe mycotic keratitis.

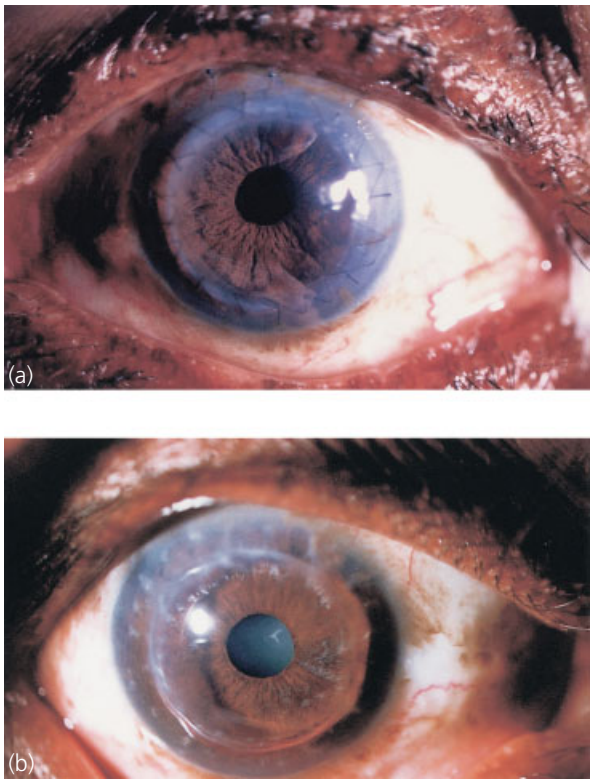

Figure 17 (a) *Keratitis due to* Fusarium solani*, 1 month after therapeutic penetrating keratoplasty. The corneal graft is clear.* **(b)** *Keratitis due to* Fusarium solani*, 4 months after therapeutic penetrating keratoplasty. The corneal graft remains clear.*

MYCOTIC SCLERITIS

Although uncommon, fungal lesions of the sclera are of great importance since they may spread from fungal infections of contiguous structures, such as the cornea or conjunctiva, or may occur secondary to trauma or surgery. Endogenous infections have also been reported. Scleritis arising due to spread of infection from keratitis due to *Absidia corymbifera* (Marshall et al. 1997), *Acremonium* spp., and *Lasiodiplodia theobromae* (Borderie et al. 1997) has been reported. Similarly, scleritis due to fungi (*Aspergillus* spp. or *Sporothrix schenckii*) may follow ocular trauma (Rodriguez-Arres et al. 1995). A unique subset of microbial scleritis following ocular surgical procedures is being increasingly reported; this is dealt with in another section (see later under Fungal ocular infections after ophthalmic surgical procedures).

One patient with *Scedosporium prolificans* corneoscleritis responded to intensive antifungal therapy and aggressive scleral debridement (Kumar et al. 1997), whereas another patient responded poorly to medical therapy (topical natamycin and amphotericin B, oral itraconazole and ketoconazole), necessitating eventual enucleation (Sullivan et al. 1994).

The outcome of scleritis due to *Scedosporium apiospermum* is also reported to be varied, with good results being obtained in some patients (Moriarty et al. 1993), and poor results in others (Taravella et al. 1997). Mycotic scleritis due to species of *Candida* or filamentous fungi (except *Fusarium*) may be treated by subconjunctival miconazole (and intravenous miconazole, if necessary). Additional remedies include oral flucytosine, oral ketoconazole, oral itraconazole, oral fluconazole, intravenous amphotericin B, topical miconazole, or topical natamycin. *Sporothrix schenckii* infection has been successfully treated with oral potassium iodide (50 mg/drop), 10 drops thrice daily, slowly increasing to 24 drops thrice daily (Brunette and Stulting 1992). Posttraumatic scleritis due to *Aspergillus fumigatus* was found to worsen in spite of oral fluconazole and topical amphotericin B therapy; cryotherapy and dura mater grafting were then performed, which appeared to control the infection (Rodriguez-Arres et al. 1995). Oral itraconazole therapy brought about resolution of inflammation in scleritis due to *Aspergillus flavus*; the patient's condition had worsened during therapy with oral ketoconazole and topical amphotericin B (Carlson et al. 1992).

INTRAOCULAR MYCOSES

Definitions

Uveitis may be defined as intraocular inflammation (Weinberg 1999). There are several systems classifying the many uveitis entities, one of which is uveitis arising due to infections caused by various microorganisms, including fungi. The intraocular inflammation caused by fungal infection usually develops slowly, is spread to the eye through the bloodstream, and consists of focal or multifocal lesions in the choroid and retina (chorioretinitis). Anterior segment inflammation is variable, but can be severe with hypopyon (Weinberg 1999). When the initial focus of intraocular fungal infection in the choroid and retina extends into the vitreous to produce inflammation, which may involve the entire internal structure of the eye, endophthalmitis results. It may be difficult, from a practical viewpoint, to discuss fungal retinitis separately from fungal endophthalmitis (Hamza et al. 1999). However, intraocular findings have been classified, based on ophthalmoscopic examination in patients with suspected ocular involvement in candidemia, into endophthalmitis (focal chorioretinitis with extension into the vitreous, intravitreal fluff balls, or vitreous haze associated with typical chorioretinal lesions), chorioretinitis (focal, deep, white chorioretinal lesions with no evidence of direct vitreous involvement), and 'nonspecific' fundus lesions (clear vitreous and no focal chorioretinitis, including cotton wool spots, retinal hemorrhages, and Roth spots) (Donahue et al. 1994). Endophthalmitis, in turn, can be divided into endogenous endophthalmitis, which arises from hematogenous spread from a focus of infection elsewhere in the body, and exogenous endophthalmitis, resulting from primary inoculation of the eye following surgery or penetrating trauma.

Etiologic agents

The major causes of intraocular mycoses are species of *Candida* (especially *Candida albicans*), *Aspergillus* (especially *Aspergillus fumigatus*), *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Scedosporium apiospermum* (*Pseudallescheria boydii*), and *Sporothrix schenckii* (Hamza et al. 1999). Species of *Fusarium* (Patel et al. 1994; Goldblum et al. 2000), *Acremonium* (Weissgold et al. 1996), *Paecilomyces* (Pettit et al. 1980; Kozarsky et al. 1984; Scott et al. 2002), zygomycetes (Orgel and Cohen 1989), and *Pneumocystis carinii* (Dugel et al. 1990; Foster et al. 1991) have also been reported to cause such lesions. Although most of these organisms produce endophthalmitis, they may also cause focal (localized) chorioretinitis or a granulomatous lesion in the iris or ciliary body (Weinberg 1999).

Frequency of occurrence

In the 1970s and 1980s, the incidence of endogenous fungal endophthalmitis in patients with candidemia or candidiasis, or both, was reported to range from approximately 10 to 40 percent. A study in the late 1980s reported that ocular lesions developed within 72 hours of the suspected onset of fungemia in approximately 90 percent of nontreated, hospitalized patients with candidemia (Brooks 1989). However, a more recent study (Scherer and Lee 1997) estimated the incidence of chorioretinal findings consistent with early endogenous fungal endophthalmitis to be 2.8 percent. This low incidence was attributed to the fact that 90 percent of the patients were being treated with systemic antifungal medication (mostly amphotericin B and/or oral fluconazole) at the time of the ophthalmological consultation. *Candida* endophthalmitis now also appears to be rare in patients with candidemia, with none of 118 adults with candidemia showing evidence of endophthalmitis, only 9.3 percent exhibiting chorioretinitis, and 20.3 percent nonspecific fundus lesions (Donahue et al. 1994). In a study of 30 hospitalized children with suspected or known systemic infections caused by *Candida* spp., all of whom had risk factors for disseminated candidiasis (broad-spectrum intravenous antibiotics, chronic debilitation with indwelling catheterization, total parenteral nutrition, immunocompromised state), none was found to have either endophthalmitis or chorioretinitis (Donahue et al. 2003). The low rate of ocular involvement in both series, compared with earlier reports, was believed to be due either to earlier treatment with antifungal agents or

to the lack of rigorous criteria for endophthalmitis in previous studies.

Predisposing factors

Intravenous drug abusers are at great risk to develop endogenous fungal endophthalmitis, probably because they may use contaminated drugs, syringes, needles, or cotton (Elliott et al. 1979). Contaminated preserved lemon juice used to dissolve heroin was found to be the cause of *Candida albicans* endophthalmitis in intravenous drug abusers in Glasgow (Shankland and Richardson 1989). Vitreous opacities may be a prominent manifestation in such individuals (Aguilar et al. 1979). In a retrospective analysis of clinical and histopathological features in 25 patients who underwent enucleation (13 with morphological features and/or positive culture for *Aspergillus* and 12 with histological evidence and/or positive culture for *Candida*), Rao and Hidayat (2001) noted a history of gastrointestinal surgery, hyperalimentation, or diabetes mellitus in nine of 12 patients with *Candida* endophthalmitis (and none of the patients with aspergillosis), whereas 12 of 13 patients with *Aspergillus* endophthalmitis, and only one of 12 patients with *Candida* endophthalmitis, had received immunosuppressive agents or had undergone organ transplants or valvular cardiac surgery. Thus, it might be possible clinically to suspect *Candida* endophthalmitis in patients who have undergone gastrointestinal surgery, and *Aspergillus* infection in those with drug-induced immune suppression or in patients who have had cardiac surgery. In another retrospective analysis of endogenous fungal endophthalmitis (where *Candida* species were the major causes), in 79 eyes of 46 patients the principal predisposing factors noted were the presence of β-D-glucan in concentrations of at least 20 pg (in 90 percent of patients), intravenous hyperalimentation (87 percent), fever of unknown origin (76 percent), male gender (74 percent), cancer (72 percent), and neutrophils in a count of at least 500/ml (67 percent) (Tanaka et al. 2001). Recent prolonged broad-spectrum antibacterials, indwelling intravenous catheters, pressure-monitoring devices, organ transplantation, and generalized immunosuppression associated with malnutrition, debilitating diseases, iatrogenic neutropenia, or corticosteroid use (Hamza et al. 1999) are other reported predisposing factors.

Diagnosis

Since anterior chamber and/or vitreous inflammation may obscure visualization of the retina, echography may help to determine the anatomic status of the retina, the extent of inflammation, the presence of choroidal detachment, and the presence and location of intraocular foreign bodies. Apart from localizing such foreign bodies, computed tomography may not be very useful, nor are electrophysiological studies (Boldt and Mieler 1996).

Since the diagnosis of exogenous fungal endophthalmitis is ultimately established by demonstrating infectious organisms in the eye, samples of aqueous and vitreous should be obtained prior to instituting therapy. A vitrectomy specimen (where as much as necessary of the vitreous is cut and removed, usually by a vitreous cutter) is preferred to a vitreous aspirate (vitreous tap) sample since the latter may fail to sample the locus of infection (Hamza et al. 1999). Anterior chamber aspirates are also a poor diagnostic technique. Although cultures of vitreous samples are more likely to yield positive results than cultures of aqueous samples, it is recommended that both samples be obtained. A conjunctival swab is of relevance only if there is a leaking filtering bleb. Fungal endophthalmitis can be confirmed by direct microscopic demonstration of fungal hyphae or yeast cells in 10 percent KOH wet mounts, or smears stained by calcofluor white and the Gram method (Brar et al. 2002). Culture is performed on appropriate media. Direct inoculation of vitreous and aqueous samples on the culture media immediately after collection is recommended. To increase the chances of recovering fungi, vitrectomy samples can be concentrated in an ultracentrifuge and then inoculated, or can be passed through cellulose membrane filters which are then applied to the culture media plates.

Fungal chorioretinitis and endogenous fungal endophthalmitis represent exceptions to the rule requiring isolation of the fungus from ocular tissue in order to establish an ocular fungal infection. For example, the presence of a typical fundus lesion, as well as a history of *Candida* spp. being cultured from blood, urine, intravascular cathethers, or other body sources days or weeks prior to the onset of symptoms, permits a presumptive diagnosis of *Candida* retinitis (Hamza et al. 1999). If nonspecific findings are present, or if there is no positive culture from an extraocular site, a diagnostic vitrectomy can be performed (Hamza et al. 1999). Similarly, in intraocular histoplasmosis and coccidioidomycosis, which are commonly associated with characteristic chorioretinal lesions, isolation of the fungus from another anatomic site, or measurement of antibody titers to the fungus, is usually deemed sufficient evidence to establish one of these fungi as the cause of the eye disease (Klotz et al. 2000). Since ophthalmic infections due to *Cryptococcus neoformans* usually occur in conjunction with meningoencephalitis, isolation of cryptococci from blood and/or cerebrospinal fluid is usually sufficient explanation for the associated eye findings (Klotz et al. 2000).

In recent years, the value of DNA-based technology in the diagnosis of fungal endophthalmitis has been evaluated. PCR assay was evaluated in the diagnosis of *Candida* endophthalmitis in four patients (Hidalgo et al. 2000); vitreous cultures were negative in two of the four

patients, but characteristic PCR products were generated in all four patient specimens, permitting the diagnosis of *Candida* endophthalmitis in all four. A protocol employing two novel panfungal primers complementary to 18S rRNA sequences of *Candida albicans*, *Aspergillus fumigatus*, and *Fusarium solani*, followed by three nested PCRs utilizing species-specific primers, was applied to ocular material from three patients with suspected endophthalmitis (Jaeger et al. 2000); a positive result for *Candida albicans* DNA and isolation of *Candida albicans* in culture was obtained from one sample and a positive result for *Candida albicans* DNA with a negative culture result was obtained in another sample (the third sample was negative for fungal DNA and was also culture negative). The two patients whose samples were positive for *Candida albicans* DNA were reported to have had clinical signs typical of fungal endophthalmitis and both patients responded to treatment with antifungal agents (Jaeger et al. 2000). Further reports are necessary before conclusions can be drawn.

Treatment

Intravitreal injections are performed in order to improve the intraocular concentration of antifungal drugs, to concentrations greater than can be achieved by systemic preparations, but toxicity may result if the dilutions are not prepared properly, or if the dilutions are injected into air-filled eyes. In the local treatment of endogenous fungal endophthalmitis, intravitreal amphotericin B is the usual recommended initial treatment, while intravitreal miconazole can be considered for those rare fungal cases resistant to amphotericin B (Flynn 2001; Song et al. 2002). Periocular amphotericin B is not commonly used because it has poor intravitreal penetration and usually causes marked conjunctival necrosis. Systemic (intravenous) amphotericin B causes serious and sometimes irreversible toxicity, hence its use is limited to very advanced endogenous fungal endophthalmitis, especially when other nonocular sites are involved (Weishaar et al. 1998; Flynn 2001).

Less toxic azole compounds, for example, fluconazole for *Candida*, can supplement intravitreal therapy and may contribute to a favorable clinical response without the risk of unwanted side effects of systemically administered amphotericin B (Borne et al. 1993; Luttrull et al. 1995; Christmas and Smiddy 1996; Flynn 2001). The possible use of intravitreal itraconazole also requires clarification. Ocular toxicity studies performed in New Zealand rabbits 5 weeks after intravitreal administration of itraconazole 10–100 μg (dissolved in 100 percent DMSO) showed no substantial retinal or histopathological changes in eyes that had been injected with 100 percent DMSO or 10 μg itraconazole, although higher doses caused focal areas of retinal necrosis (Schulman et al. 1991). Based on the results of an experimental study, Yoshizumi and Banihashemi (1988) suggested that a single intravitreal dose of ketoconazole ($\leqslant$540 μg) in DMSO could be safely used for fungal endophthalmitis. Intravenous administration of fluconazole (5 or 25 mg/kg) in albino rats resulted in aqueous, vitreous, and serum levels (1 hour after administration) of 2.87, 1.72, and 4.6 μg/ml (5 mg/kg) and 14.9, 7.05, and 20.6 μg/ml (25 mg/kg), respectively; the intraocular penetration was moderately enhanced by vitrectomy (Mochizuki et al. 1992). In vitro electroretinograms (ERG) remained unchanged after perfusion with fluconazole (20 μg/ml) while the in vivo ERG and visual evoked potentials were unchanged after daily fluconazole (25 mg/kg) for 8 days, suggesting good safety profile. Following intravenous inoculation of fluconazole 20 mg/kg as a single dose or 20 mg/kg every 12 hours for four doses in nonpigmented rabbits, fluconazole concentrations in the aqueous, vitreous, CSF, and serum were determined by a microbiological assay; the penetration of fluconazole in all the anatomic compartments was found to be >70 percent of that in serum (Mian et al. 1998). Since the CSF and ocular pharmacokinetic parameters closely resemble each other, either could be used as a surrogate for the other (Mian et al. 1998). A biodegradable polymeric scleral implant containing fluconazole was reported to be a promising intravitreal drug delivery system to treat fungal endophthalmitis (Miyamoto et al. 1997). Scleral implants loaded with 10, 20, and 30 percent doses gradually released fluconazole over 4 weeks in vitro while those with 50 percent doses released most of the drug in one week; implants with 30 percent fluconazole that were studied in pigmented rabbits resulted in vitreous concentrations of fluconazole (sustained for 3 weeks) sufficient to inhibit *Candida albicans*. Intravitreal injection of up to 100 μg fluconazole per 0.1 ml of vitreous did not produce biomicroscopic, ophthalmoscopic, electroretinographic, or light microscopic evidence of intraocular toxicity, even 8 days after inoculation (Schulman et al. 1987).

The typically slow replication of fungal elements may contribute to a less favorable response to intravitreal antifungal therapy alone; therefore, pars plana vitrectomy is often selected for initial therapy to obtain a satisfactory specimen for culture and to remove vitreous infiltrates. Vitrectomy for the treatment of fungal endophthalmitis has been advocated in all but very mild or exceptional cases. The indications for vitrectomy in patients with fungal chorioretinitis and endophthalmitis are advanced cases with extensive vitreous involvement and poor response to systemic antifungal therapy (Pettit et al. 1996; Smiddy 1998). The potential benefits of vitrectomy include:

- debulking of inflammatory and infectious material from the vitreous
- acquisition of a larger sample for laboratory study
- potential for concentrating the sample by centrifugation or filtration to give a better yield on culture

- an opportunity for intravitreal injection of antifungals
- removal of the scaffolding for vitreoretinal traction bands and epiretinal membranes that can contribute to late-developing macular pucker and retinal detachment (Pettit et al. 1996).

However, vitrectomy and intravitreal injections are better avoided in cases of neonatal endophthalmitis.

Essman et al. (1997) performed a retrospective analysis of treatment outcomes of 20 eyes (18 patients) with culture-proven endogenous fungal endophthalmitis (17 due to *Candida* species, three due to *Aspergillus* spp.) seen over a 10-year period. After initial examination, 17 of 20 eyes underwent pars plana vitrectomy and 19 of 20 received intravitreal amphotericin B; 16 patients received systemic antifungals (oral ketoconazole, oral fluconazole). Thirteen (76 percent) of 17 eyes with *Candida* infection achieved visual acuities equal to or better than 20/400, while none of the three eyes with *Aspergillus* infection achieved such a visual acuity. Based on these results, these authors recommended pars plana vitrectomy, intravitreal amphotericin B, and administration of appropriate systemic antifungals (oral fluconazole for *Candida* infections) in managing patients with marked vitreous infiltrates due to endogenous fungal endophthalmitis.

Recommendations for postoperative and post-traumatic exogenous fungal endophthalmitis (Pflugfelder et al. 1988) include surgical measures (excision of clinically involved tissue, vitrectomy if there is visible vitreous involvement, retention of the intraocular lens unless there is extensive infiltration around the lens, or recurrent infection) and medical therapy:

- intraocular amphotericin B 5–10 μg in regions of maximal involvement, repeatable
- miconazole 25–50 μg in patients with *Paecilomyces lilacinus* infection or in treatment failure with amphotericin B
- topical (hourly) 5 percent natamycin, or topical (hourly) 0.15 percent and subconjunctival 500–1000 μg amphotericin B or topical (hourly) 1 percent and subconjunctival 5–10 mg miconazole, if there is corneal, scleral, or anterior chamber involvement
- systemic (oral) ketoconazole 400–600 mg/day.

Recommendations for exogenous fungal endophthalmitis developing from fungal keratitis include surgery (penetrating keratoplasty for deep keratitis with retrocorneal or anterior chamber involvement unresponsive to medical therapy, retention of the iris and lens if possible, or iridectomy, lensectomy, and vitrectomy if there is clinical evidence of infiltration of these structures, or if there is recurrence of the endophthalmitis) and medical therapy:

- intravitreal amphotericin B 5–10 μg if the anterior chamber or vitreous is involved
- topical hourly natamycin 5 percent, topical 0.15 percent amphotericin B or topical 1 percent miconazole
- subconjunctival miconazole or amphotericin B
- oral ketoconazole.

The role of intravitreal corticosteroids remains controversial, but they can be considered if appropriate antimicrobial coverage of the causative organism can be assured (Flynn 2001). Interestingly, Majji et al. (1999) reported on the role of intravitreal dexamethasone in the management of 20 patients with exogenous fungal endophthalmitis; all 20 patients had undergone pars plana vitrectomy, and had received intravitreal amphotericin B and oral ketoconazole, and some patients had also received intravitreal dexamethasone. Overall, nine of the 20 patients achieved a final visual acuity of better than counting fingers at 3 metres. The rate of clearance of inflammation was better in eyes that had received intravitreal dexamethasone. Also, a favorable visual outcome was achieved in a higher number of eyes that had received dexamethasone, compared to eyes not receiving dexamethasone; however, this difference was not statistically significant. These authors cautioned that while the results of their retrospective study suggested that corticosteroids may be beneficial in promoting faster clearance of inflammation in fungal endophthalmitis, the sensitivity of the fungi to antifungals, the dose and timing of steroid, and institution of effective antifungal medication prior to the use of corticosteroids were all essential factors which needed to be examined further in a prospective manner.

Specific types of intraocular mycoses due to different etiologic agents

CANDIDA SPECIES

Candida spp. are common causes of disseminated disease in drug abusers, in severely ill hospitalized patients, and in those patients who are immunocompromised (Donahue et al. 1994). Hence, it is not surprising that in patients with endogenous fungal endophthalmitis, the most common causative organism is *Candida* spp. (Flynn 2001). Endogenous *Candida* endophthalmitis differs from endogenous bacterial endophthalmitis in being more often slowly progressive, sometimes capable of successful management by systemic therapy alone, and in having a more favorable visual prognosis (Brod et al. 1990; Christmas and Smiddy 1996; Essman et al. 1997; Flynn 2001). *Candida albicans* is the most common fungal pathogen causing chorioretinitis or endophthalmitis, while other *Candida* spp., including *Candida glabrata* and *Candida parapsilosis*, are less commonly implicated (Parke et al. 1982; Pettit et al. 1996). This greater tendency of *Candida albicans*, compared to other *Candida* spp., to produce chorioretinitis is thought to be because *Candida albicans* rapidly forms germ tubes in serum (whereas other *Candida* spp. do not), which lodge in the choriocapillaries more easily and more frequently

than other species, or due to differences in the patterns of phospholipase and protease production among different *Candida* spp. (Moyer and Edwards 1993).

Although a number of factors (mentioned above) may predispose to endogenous fungal endophthalmitis, specific risk factors for endophthalmitis due to *Candida* spp. appear to be major surgery involving the gastrointestinal system, parenteral hyperalimentation, and diabetes mellitus (Rao and Hidayat 2001). *Candida* endophthalmitis has also been reported after induced abortion (Chen et al. 1998) and in association with retinopathy in premature infants (Gago et al. 2002). Cataract and intraocular inflammation, and progressive retinopathy of prematurity and tractional retinal detachment, secondary to *Candida* septicemia were also recently reported in a markedly premature infant (Shah et al. 2000); pars plana vitrectomy and lensectomy revealed lens material infiltrated by *Candida*-like yeast forms and pseudohyphae. Song et al. (2002) reported the occurrence of endogenous fungal retinitis, presumed to be due to a *Candida* sp., in a 3-year-old boy who had acute lymphocytic leukemia and a skin rash proven by culture to be due to a *Candida* sp.

The most characteristic ophthalmoscopic sign of *Candida* chorioretinitis is a creamy-white, well-circumscribed lesion involving the retina and choroid in the posterior pole, which may be single or multiple, unilateral or bilateral; the lesions may exist in a satellite pattern, and retinitis may progress to vitreous involvement. Vitreous opacities are typically yellow–white, may be connected by strands, giving a 'string of pearls' appearance, and may be so severe as to obscure the view of the fundus, thereby making the clinical diagnosis difficult (Aguilar et al. 1979; Hamza et al. 1999). In a study of 12 eyes of 12 patients that had been enucleated due to *Candida* endophthalmitis, it was noted that the initial presentation of *Candida* infection was as a vitritis or vitreoretinitis in seven, panuveitis in three, and endophthalmitis in two patients (Rao and Hidayat 2001). Intraretinal hemorrhages may also occur; in fact, focal retinal necrosis and scarring combined with vitreoretinal membrane formation and contraction are the major causes of permanent visual loss (Aguilar et al. 1979; Barrie 1987; Brod et al. 1990). Choroidal neovascularization is a potential cause of late visual loss in patients who have had *Candida albicans* sepsis and endogenous *Candida albicans* chorioretinitis (Jampol et al. 1996). *Candida parapsilosis* may cause a low-grade postcataract extraction endophthalmitis (Hamza et al. 1999), while multifocal endophthalmitis due to *Candida tropicalis* has been reported as the only initial manifestation of pacemaker endocarditis (Shmuely et al. 1997).

Candida retinitis or endogenous endophthalmitis should be suspected in any patient with one of the known predisposing conditions and who presents with progressive chorioretinitis or posterior uveitis. Criteria for the diagnosis of such an infection are discussed above. In addition, detection of anti-*Candida* antibodies in aspirates of anterior chamber fluid may be useful in establishing a diagnosis (Mathis et al. 1988). In histopathological studies on 12 eyes of *Candida* endophthalmitis, fungi were located in the vitreous alone in seven patients, in the vitreous and retina in two, in the vitreous, retina, subretina, and choroid in two, and in the iris and ciliary body in one (Rao and Hidayat, 2001).

Based on a retrospective analysis of treatment outcomes in 20 eyes of 18 patients, Essman et al. (1997) recommended pars plana vitrectomy, intravitreal amphotericin B, and administration of appropriate systemic antifungals (oral fluconazole for *Candida* infections) in managing patients with marked vitreous infiltrates due to endogenous fungal endophthalmitis. However, other therapeutic approaches have been described for chorioretinitis and endophthalmitis due to *Candida* spp. Laatikainen et al. (1992) described a patient with bilateral *Candida* endophthalmitis who was treated with oral fluconazole, and in whom vitrectomy and intravitreal amphotericin B was given for one eye only; both eyes healed equally well. Borne et al. (1993) described a patient with postoperative endophthalmitis due to *Candida parapsilosis* in whom vitrectomy and intravitreal amphotericin B had failed, whereas oral fluconazole resulted in a successful outcome. Luttrull et al. (1995) described rapid (within 24 hours of initiation of therapy) and dramatic responses to oral fluconazole therapy only (400 mg/day) in one patient with culture-proven and in three patients with presumed endogenous *Candida* endophthalmitis. Christmas and Smiddy (1996) reported that pars plana vitrectomy, oral fluconazole therapy (100 mg once or twice daily for 3–6 months), and subconjunctival gentamicin and dexamethasone were sufficient to bring about clinical resolution of lesions and visual improvement in six eyes of five patients with *Candida* endophthalmitis (four eyes culture-positive for *Candida albicans*, one eye culture-positive for *Candida tropicalis*, and one eye direct microscopy positive but culture-negative) without the need for intravitreal amphotericin B or fluconazole therapy. In one patient, oral antifungals alone had been unsuccessful before pars plana vitrectomy, while in two other patients with asymmetric bilateral vitritis, the second eye had not improved despite 11 days of oral fluconazole therapy. These authors concluded that vitrectomy and oral fluconazole without intravitreals could be recommended for successful management of endogenous *Candida* endophthalmitis. More recently, Mora et al. (2002), based on their experience of management and therapy of fungal endophthalmitis in 17 patients (27 eyes) seen over a 9-year period, concluded that while oral fluconazole was successful in managing mild fungal endophthalmitis, additional vitrectomy (sometimes more than once) and intraocular amphotericin B were necessary for more severe cases. Presumed bilateral endophthalmitis due to *Candida* spp. that developed in an infant with bilateral

posterior stage 3 retinopathy of prematurity was successfully eradicated from each eye by vitrectomy with instillation of 5 μg amphotericin B (Gago et al. 2002). In patients who have developed choroidal neovascularization secondary to *Candida* chorioretinitis, laser photocoagulation or surgical excision of the neovascular complex may be of benefit in selected cases (Jampol et al. 1996).

ASPERGILLUS SPECIES

Aspergillus spp. may cause exogenous or endogenous endophthalmitis. Narang et al. (2001), who reviewed data pertaining to 27 patients with exogenous fungal endophthalmitis, principally due to *Aspergillus* spp., noted substantial corneal involvement in 14 eyes; multivariate analysis revealed that this was the single most important risk factor in determining final visual outcome. Tabbara and al-Jabarti (1998) reported an outbreak of ocular aspergillosis (*Aspergillus fumigatus*) after cataract surgery; the outbreak was finally found to be associated with ongoing hospital construction. All five patients developed endophthalmitis, while two patients also had superior limbal, scleral, and corneal infiltration. Endogenous *Aspergillus* endophthalmitis has been reported in patients who have received immunosuppressive agents or who have undergone organ (heart, lung, or liver) transplants or valvular cardiac surgery (Weishaar et al. 1998; Rao and Hidayat 2001) and intravenous drug abusers (Weishaar et al. 1998). Kalina and Campbell (1991) reported endophthalmitis in a patient suffering from chronic lymphocytic leukemia who had presented with acute visual loss and redness in one eye. Although results of stains and cultures of anterior chamber fluid were negative, cultures from antemortem sputum and skin samples were positive for *Aspergillus terreus* while postmortem histological results showed extensive invasion of the posterior vitreous, retina, choroid, and anterior optic nerve by filamentous fungi presumed to be *Aspergillus terreus*. Predisposing systemic conditions may modify the probability of dissemination, risk of mortality, and role for systemic treatment.

The clinical features of endogenous *Aspergillus* endophthalmitis, the ocular presentation, and findings often are characteristic and provide possible diagnostic utility. In a retrospective analysis of ten patients (12 eyes) with culture-proven endogenous *Aspergillus* endophthalmitis, Weishaar et al. (1998) reported that all patients had a 1–3-day history of pain and marked loss of visual acuity in the involved eyes and that varying degrees of vitritis were present in all 12 eyes; in eight of 12 eyes, a central macular chorioretinal inflammatory lesion was present, and an inferior gravitational layering of inflammatory exudate in either or both the subhyaloid and subretinal space. In another retrospective analysis of 13 patients with histopathologically proven *Aspergillus* intraocular infection, the findings at presentation were endophthalmitis in four, panuveitis, acute retinal necrosis, chorioretinitis, or vitritis/vitreoretinitis in two each, and as granulomatous anterior uveitis in one patient (Rao and Hidayat 2001). The severity of retinal involvement in endogenous *Aspergillus* endophthalmitis may range from subretinal or subhyaloid infiltrates to vascular occlusion and full-thickness retinal necrosis; intraretinal hemorrhages are frequent. Rao and Hidayat (2001) reported that in 13 eyes with *Aspergillus* endophthalmitis, fungi were seen in the vitreous, retina, subretina, and choroid in eight, in the vitreous alone in three, and in the vitreous and retina in two. These authors concluded that, histopathologically, the vitreous is the primary focus of infection for *Candida*, whereas it appears that *Aspergillus* grows preferentially along the subretinal pigment epithelium and subretinal space.

Compared with *Candida* spp., *Aspergillus* endophthalmitis is typically more difficult to diagnose because:

- skin test and serology are unreliable
- the diagnostic yield of blood cultures, pulmonary radiographic studies, and echocardiograms is low
- isolation from blood cultures is difficult even in patients who are immunosuppressed with definite dissemination
- systemic manifestations are often lacking in intravenous drug abusers with this infection (Lance et al. 1988; Weishaar et al. 1998).

A diagnostic vitreous aspirate for cytology and culture isolation is usually necessary to identify this etiologic agent (Lance et al. 1988). However, diagnosis of endogenous *Aspergillus* endophthalmitis by anterior chamber or vitreous aspirates alone may be unreliable (Weishaar et al. 1998). According to Rao and Hidayat (2001), since aspergillosis clinically presents with extensive areas of deep retinitis/choroiditis, vitreous biopsy might not always yield positive results. Pars plana vitrectomy specimens assisted by Gram or Giemsa stains appear to have the highest yield of positive cultures for *Aspergillus*; in the series of Weishaar et al. (1998), eight of nine previously untreated eyes had a positive culture from the vitrectomy specimen. Anand et al. (2001) compared PCR against the conventional mycological methods of microscopy and culture for growth of fungi in the diagnosis of *Aspergillus* endophthalmitis in 27 intraocular specimens from 22 patients with suspected fungal endophthalmitis (which were proven to be nonbacterial in origin); 10 patients with non-infective intraocular disorders were the controls. None of the controls was positive by microscopy, culture, or PCR. Among the 27 test samples, four were positive by culture for *Aspergillus* spp. and were also positive by PCR. In addition, PCR detected and identified *Aspergillus* spp. in two culture-negative specimens. The average time required for culture and identification of *Aspergillus* was 10 days, whereas PCR was able to yield results in just 24 hours.

The optimal treatment for endogenous *Aspergillus* endophthalmitis remains controversial. This is in part due to the fact that, in contrast to the outcome of endophthalmitis due to *Candida* spp., the mortality is high in patients with *Aspergillus* endophthalmitis, particularly those who have received organ transplants or who have undergone cardiac surgery (Rao and Hidayat 2001). Moreover, endogenous *Aspergillus* endophthalmitis during systemic aspergillosis usually requires more than systemic treatment to achieve resolution of the ocular infection. The visual outcome in these patients is influenced primarily by the propensity of *Aspergillus* for initial macular choroidal involvement. Based on their results in treatment of endogenous *Aspergillus* endophthalmitis, Weishaar et al. (1998) recommended the following:

- pars plana vitrectomy when vitreous seeding is present to remove the focus of infection and to improve the likelihood of a positive culture, but not necessarily in fellow eyes in which only isolated chorioretinal lesions are present and when the diagnosis can be made from evaluation of the first eye
- amphotericin B (5–10 μg) as intravitreal antifungal treatment
- intravitreal dexamethasone 400 μg (although controversial) to reduce the marked intraocular inflammation in many of these eyes
- intravenous amphotericin B to supplement the effectiveness of intravitreal amphotericin B therapy and to treat proven or clinically suspected systemic aspergillosis
- a well-tolerated and less toxic systemic medication (example, itraconazole) to supplement intravitreal amphotericin B in patients with only endogenous *Aspergillus* endophthalmitis and no systemic manifestations
- repeat intravitreal amphotericin B (5–10 μg) and possibly repeat vitrectomy in patients with persistent vitreous infiltrates and suspected recurrent disease after initial treatment.

Using this regimen to treat 12 eyes of 10 patients with endogenous *Aspergillus* endophthalmitis, final visual acuities of 20/25 to 20/200 were attained in three eyes without central macular involvement; in eight eyes with initial central macular involvement, final visual acuities were 20/400 in three eyes and 5/200 or less in four eyes. Two painful eyes with marked inflammation, hypotony, and retinal detachment were enucleated (Weishaar et al. 1998).

Lance et al. (1988) reported a distinctive case of endogenous endophthalmitis due to *Aspergillus flavus* in an intravenous drug abuser in which the patient recovered useful vision after resolution of the endophthalmitis, which did not recur in spite of extensive retinal and vitreous involvement, since vitrectomy and intravitreal injection of amphotericin B were performed within 48 hours of presentation, followed by intravenous administration of amphotericin B several days later. Unfortunately, others have reported less favorable results. Coskuncan et al. (1994) reported on two cases of *Aspergillus flavus* retinitis (proven by recovery of the fungi in culture of vitreous samples) in patients who had undergone bone marrow transplantation 120 days before; the eyes responded poorly to antifungals. Tabbara and al-Jabarti (1998) reported an outbreak of culture-proven exogenous endophthalmitis due to *Aspergillus fumigatus* in five patients who had undergone cataract extraction during hospital construction; severe postoperative uveitis occurred in all five patients 4–15 days postsurgery and failed to subside with topical corticosteroid therapy. One patient received only antifungals (intravitreal and subconjunctival miconazole, intravenous and intravitreal amphotericin B), two patients had pars plana vitrectomy and intravitreal amphotericin B, while one patient had only pars plana vitrectomy. Unfortunately, evisceration or enucleation had to be ultimately performed for all five patients. Brar et al. (2002) reported the occurrence of *Aspergillus niger* endophthalmitis 9 weeks after cataract surgery, with extension to the cornea; the outcome of the infection was unknown since the patients did not return for follow-up evaluation.

DEMATIACEOUS FUNGI

Fungal endophthalmitis has been reported to be caused by dematiaceous fungi such as *Alternaria alternata* (Rummelt et al. 1991), *Curvularia lunata* (Kaushik et al. 2001), *Exophiala jeanselmei* var. *jeanselmei* (Hofling-Lima et al. 1999) following cataract surgery, and by *Lasiodiplodia theobromae* (Borderie et al. 1997) and *Microsphaeropsis olivacea* (Shah et al. 2001) following keratitis. The prognosis in such infections is unsatisfactory. In the cases reported by Kaushik et al. (2001) and Shah et al. (2001), the intraocular part of the infection resolved quickly after intraocular debridement, and intravitreal, topical, and systemic antifungals, but the corneal infection persisted.

Hofling-Lima et al. (1999) reported on two cases of late endophthalmitis caused by *Exophiala jeanselmei* var. *jeanselmei* after cataract surgery. Although intravitreal and anterior chamber amphotericin B were used in both cases, with initial resolution of the lesions, recurrence occurred in both instances, leading to endophthalmitis.

SCEDOSPORIUM APIOSPERMUM (PSEUDALLESCHERIA BOYDII)

Endogenous endophthalmitis due to *Scedosporium apiospermum* (teleomorph *Pseudallescheria boydii*) also appears to carry a poor prognosis. McGuire et al. (1991) reviewed the clinical and other features of 17 patients with ocular infections due to this fungus reported up to 1991. Numerous predisposing factors in these patients included trauma (penetrating injury, burn, or foreign body), a chronic underlying disease (diabetes mellitus or systemic lupus erythematosus), drowning with aspira-

tion, immunosuppression (for renal transplantation), multiple surgical procedures, and cataract surgery. The clinical findings of the 17 infected eyes included ten endophthalmitides, five corneal ulcers, and two orbital cellulitides. *Scedosporium apiospermum* (reported as *Pseudallescheria boydii*)was cultured in 17 of the 17 reported cases; ocular histopathological descriptions reported hyphae and/or conidia in 13 of the 17 cases. Therapeutic surgical procedures included enucleation for five of the 17 eyes, with one instance each of lysis of adhesions and resection of a mycetoma, orbital debridement, evisceration, lensectomy, and keratoplasty; one patient required a sclerotomy, iridectomy, lensectomy, and synechiectomy; two patients underwent a vitrectomy; and two underwent orbital debridement. Antifungal agents were used in 14 of the 17 patients; however, the etiologic diagnosis was delayed in all 17 patients. Seven patients were treated with only amphotericin B; one required enucleation to eradicate the infection, but there were no deaths in this treatment group. Four patients were treated with amphotericin B initially, then treated with miconazole; two underwent enucleation and two died. One patient had partial treatment with amphotericin B, then miconazole, and finally fluconazole; this patient underwent enucleation before death. In this series of ocular infections, four patients (all disseminated disease) died. In an experimental study by the same group of workers, the fungus was found to produce a severe endogenous endophthalmitis in nine of 17 immunosuppressed rabbits following its injection into the carotid artery; three instances of lens/lens capsule destruction were seen in this group (McGuire et al. 1991). These authors concluded that ocular infections due to *Pseudallescheria boydii* (*Scedosporium apiospermum*) mimic both clinically and histologically those caused by *Aspergillus fumigatus*. More recent reports confirm the severity of endogenous endophthalmitis due to *Scedosporium apiospermum*. McKelvie et al. (2001) reported about two patients with acute myeloid leukemia and neutropenia who developed endophthalmitis due to *Scedosporium apiospermum* and who ultimately succumbed to overwhelming fungal septicemia in spite of treatment with amphotericin B alone in one patient, and combined amphotericin B and fluconazole in the other. Luu et al. (2001) reported the development of endophthalmitis due to this fungus (in spite of concurrent intravenous amphotericin B therapy) in a patient who had undergone liver transplantation, and who had a ring-enhancing brain lesion; the inflammation progressed in spite of pars plana vitrectomy and intravitreal amphotericin B, and the patient died of complications due to brain abscess.

COCCIDIOIDES IMMITIS

Intraocular coccidioidomycosis, which may occur in otherwise healthy individuals, usually presents with multiple, yellow–white, juxtapapillary chorioretinal lesions with pigmented borders, but retinal exudates or serous retinal detachment may also occur (Rodenbiker and Ganley 1980). Fluconazole appears to be useful in the treatment of this condition. Luttrull et al. (1995) reported successful treatment of bilateral multifocal choroiditis and unilateral granulomatous iridocyclitis due to *Coccidioides immitis* in a patient who received 600 mg fluconazole daily. Cunningham et al. (1998) described two patients with intraocular coccidioidomycosis, one with a unilateral, granulomatous iridocyclitis with multiple iris nodules and a large vascularized anterior chamber, and the other with papilledema and multifocal choroiditis, in whom the diagnosis was established by detection of *Coccidioides immitis* spherules in skin biopsy samples; the patients were successfully treated with local and systemic amphotericin B and oral fluconazole.

BLASTOMYCES DERMATITIDIS

Intraocular blastomycosis is an unusual occurrence. Choroidal involvement (manifesting as bilateral, multiple, yellow–white posterior fundus lesions) has been reported to occur in association with miliary or disseminated blastomycosis (Sinskey and Anderson 1955; Lewis et al. 1988), while isolated endophthalmitis (Safneck et al. 1990) and panophthalmitis (Font et al. 1967) due to *Blastomyces dermatitidis*, without any systemic manifestations, has also been reported. In a case described by Bond et al. (1982), a patient with biopsy-proven sarcoidosis developed fever, skin lesions and anterior uveitis, vitritis, and a large posterior yellow, elevated choroidal lesion in one eye and three white posterior small choroidal lesions in the other eye. Although a diagnosis of blastomycosis was established by the biopsy of the skin lesion, it was unclear whether the ocular manifestations in this patient were due to blastomycosis or sarcoidosis. Li et al. (1998) reported a patient with concurrent unilateral endophthalmitis and orbital cellulitis proven by histological findings and by culture to be due to *Blastomyces dermatitidis*. Amphotericin B therapy was shown to produce a rapid resolution of choroidal and extraocular lesions in one patient (Lewis et al. 1988), without any recurrence over a 6-month follow-up period. However, in general, the therapy of intraocular blastomycosis appears to be unrewarding, with enucleation of the affected eye having to be performed to control the infection in most instances (Sinskey and Anderson 1955; Font et al. 1967; Safneck et al. 1990; Li et al. 1998). Intraocular dissemination of blastomycosis should be suspected in the differential diagnosis of endophthalmitis in patients with previous or active pulmonary lesions of equivocal nature. Early diagnosis and prompt treatment with antifungal medications are essential.

CRYPTOCOCCUS NEOFORMANS

Intraocular cryptococcosis usually results from cryptococcal septicemia with severe meningeal infection; such

sequelae may be seen in patients with AIDS. Cohen and Glasgow (1993) reported the occurrence of sudden, simultaneously bilateral blindness in a patient with AIDS who had cryptococcal meningitis; although the sudden, bilateral visual loss in this patient was ultimately found to have been caused by focal but fulminant necrosis of both optic nerves, the authors believed that the presence of cryptococcal organisms throughout the basal meninges and in the sheaths of both optic nerves suggests that cryptococcosis may produce visual loss by damaging multiple areas of the anterior visual pathway. Agarwal et al. (1991) reported the occurrence of retinitis (presumably due to cryptococcal infection) following disseminated cryptococcosis in a patient who had received a renal allograft. However, Hester et al. (1992) described isolated ocular cryptococcosis in a 62-year-old female immunocompetent patient. Hence, ocular cryptococcal infection must be suspected, even in the absence of predisposing factors or systemic findings. The diagnosis of cryptococcal chorioretinitis is a presumptive one in a patient with characteristic fundus lesions, with or without vitritis, and documented cryptococcal meningitis or disseminated cryptococcosis (Klotz et al. 2000). In one patient, transscleral needle biopsy of a subretinal mass was used to establish the diagnosis of subretinal cryptococcosis (Hester et al. 1992). A vitreous tap or biopsy may be done if vitritis is present. Cryptococcal chorioretinitis can be treated with intravenous amphotericin B (Hester et al. 1992) or oral fluconazole (Agarwal et al. 1991). Vitrectomy may be needed if chorioretinitis progresses to endophthalmitis.

PARACOCCIDIOIDES BRASILIENSIS

Ocular paracoccidioidomycosis usually manifests as lesions in the eyelid and conjunctiva (Silva et al. 1988). Cases of choroidal granuloma and endophthalmitis have been described, but few have been histopathologically proven (Bonomo et al. 1982). Finamor et al. (2002) recently described the occurrence of ocular and central nervous system paracoccidioidomycosis in a pregnant woman with AIDS. The patient presented with an acute and painful eye, and ophthalmological examination revealed unilateral severe iridocyclitis, severe vitritis, and a granulomatous chorioretinal lesion adjacent to and involving the optic nerve; the lesions evolved after a week to iris neovascularization, neovascular glaucoma, and retinal detachment. The eye was enucleated due to intense pain. Macroscopic study of the enucleated eye showed a total retinal detachment with subretinal exudate and a white mass in the vitreous cavity displacing the lens to the anterior chamber. Histopathological examination of the enucleated eye, as well as a biopsy of an oral lesion, revealed a chronic granulomatous inflammation with epithelioid cells, multinucleated giant cells, and several round yeasts exhibiting 'ship's wheel' external budding in sections stained by periodic acid–Schiff and Grocott methenamine silver stains, an appearance typical of *Paracoccidioides brasiliensis*. With the diagnosis of disseminated ocular paracoccidioidomycosis, the patient was treated with trimethoprim-sulfamethoxazole with a satisfactory outcome and reduction in the size of the brain lesion (Finamor et al. 2002).

HISTOPLASMA CAPSULATUM

The 'presumed ocular histoplasmosis syndrome' is characterized by the presence of multifocal choroiditis scattered throughout the fundus, the peripapillary area, and sometimes in the macular area, with some lesions exhibiting healing with variable chorioretinal scarring (Katz et al. 1997). This syndrome is not associated with intraocular inflammation, and is well tolerated by the eye, unless complications of subretinal neovascularization, such as progressive visual loss, arise (Gonzales et al. 2000). In such instances, vitreoretinal surgical techniques have been used to remove the subfoveal neovascular membranes while preserving the overlying neurosensory retina, and thus preserving central visual acuity (Thomas and Kaplan 1991). *Histoplasma capsulatum* var. *capsulatum* has been isolated from the eyes of patients suffering from this syndrome, suggesting that this fungus is the etiologic agent (Katz et al. 1997), although this is a contentious point. However, *Histoplasma capsulatum* var. *capsulatum* has been implicated as the etiologic agent in several other intraocular lesions. Specht et al. (1991) reported on ocular histoplasmosis with retinitis in a patient with AIDS and disseminated histoplasmosis, who had complained of a hazy spot in the vision of his left eye; distinct creamy-white intraretinal and subretinal infiltrates were visualized in both eyes. After the patient succumbed to his illness, light microscopy of his eyes removed at autopsy revealed that the most prominent colonization of ocular tissue by yeasts was in the retinae and optic nerves, with focal choroiditis near the retinal lesions. These lesions showed variable numbers of lymphocytes and histiocytes, and yeasts with a morphology suggestive of *Histoplasma capsulatum* var. *capsulatum*, free or phagocytized within cells, in all layers of the retinal lesions, sometimes with extension to the subretinal and subhyaloid spaces. One eye also exhibited necrotizing granulomatous cyclitis with aggregates of yeasts. Histoplasmic optic neuritis was reported by both Macher et al. (1985) and Specht et al. (1991), while histoplasmic cyclitis was also noted by Specht et al. (1991). Endophthalmitis due to *Histoplasma capsulatum* var. *capsulatum* in a patient with AIDS has also been reported (Gonzales et al. 2000).

SPOROTHRIX SCHENCKII

Risk factors for endophthalmitis due to *Sporothrix schenckii* include AIDS (Kurosawa et al. 1988) and trauma (Witherspoon et al. 1990); however, this ocular

infection may occur even without trauma or systemic infection (Cartwright et al. 1993). Vieira-Dias et al. (1997) reported the occurrence of concomitant ocular and cutaneous sporotrichosis, where the fungus was isolated from skin lesions and the aqueous humor. Endophthalmitis due to *Sporothrix schenckii* usually presents initially as a granulomatous uveitis, which may be treated with corticosteroids, therein leading to progression of the lesion and resulting in frank endophthalmitis (Kurosawa et al. 1988) or scleral perforation (Cartwright et al. 1993). Up to 1990, 17 episodes of endophthalmitis due to *Sporothrix schenckii* had been reported (Witherspoon et al. 1990). Curi et al. (2003) described the occurrence of fluffy vitreous opacities and a retinal granuloma in a young man who presented with disseminated ulcerated skin lesions that were proven by biopsy and by culture to be due to *Sporothrix schenckii*. It is important to remember that although intraocular infection due to *Sporothrix schenckii* is uncommon, it can occur in cases of disseminated sporotrichosis. Systemic therapy with potassium iodide or itraconazole is a successful means to control skin and ocular sporotrichosis.

ACREMONIUM SPECIES

Exogenous endophthalmitis due to *Acremonium* spp. may arise due to contamination from a common environmental source. Weissgold et al. (1996) described four patients who presented after cataract surgery with delayed-onset endophthalmitis caused by *Acremonium kiliense* with in vitro sensitivity to amphotericin B. In all patients, ocular infection was recalcitrant to single-dose intravitreous amphotericin B injection (5 μg) and systemic administration of fluconazole. These patients subsequently responded to vitrectomy followed by additional intravitreous amphotericin B injection. These authors concluded that single-dose administration of intravitreous amphotericin B may be inadequate treatment for fungal endophthalmitis caused by *Acremonium kiliense*, and that vitrectomy with repeated intravitreous administration of amphotericin B may be necessary to eradicate intraocular infection caused by this organism.

ZYGOMYCETES

Orgel and Cohen (1989) described the first case of postoperative zygomycete endophthalmitis that occurred after uncomplicated phacoemulsification and the insertion of a posterior chamber intraocular lens. Diagnosis, in the presence of negative aqueous and vitreous cultures, was confirmed by immunofluorescence staining of an anterior chamber inflammatory mass. Successful treatment of the eye with 20 μg intraocular amphotericin B may have been made possible in part by the fact that the posterior capsule remained intact, keeping the eye bicompartmental. The evolution of fundus changes from edema of the optic disk and peripapillary retina to optic atrophy and chorioretinal pigmentary changes has been rarely reported in rhino-orbital zygomycosis (Newman and Kline 1997; Kadayifcilar et al. 2001). Unique chorioretinal changes caused by choroidal ischemia secondary to rhino-orbital zygomycosis have also been reported (Kadayifcilar et al. 2001).

FUSARIUM SPECIES

Intraocular lesions due to *Fusarium* spp. may occur in patients with leukemia or as a consequence of the progression of corneal lesions. Patel et al. (1994) reported on a patient with acute lymphocytic leukemia with both endogenous *Fusarium* endophthalmitis and leukemic ocular infiltrates who presented with sudden visual loss in one eye, which exhibited a dense white placoid infiltrate in the macula extending into the vitreous, and with an iris nodule and hypopyon in the other eye. Histopathological studies performed after the patient's death from multisystem failure disclosed panophthalmitis with *Fusarium* invading all the ocular coats in the right eye, while in the left eye there were leukemic infiltrates in the iris, anterior chamber, and trabecular meshwork. These authors postulated that the ocular destructiveness of *Fusarium* spp. may be caused by marked mycotic vascular invasion and occlusion with consequent infarction and necrosis of ocular tissues. Dursun et al. (2003) reported that 10 out of a total of 159 patients with keratitis due to *Fusarium* spp. (seven due to *Fusarium oxysporum*, two to *Fusarium solani*, and one to a *Fusarium* sp.) progressed to endophthalmitis. Cultures of aqueous and intraocular tissues grew *Fusarium* in eight cases, whereas vitreous cultures were positive in two. Nine cases had preexisting risk factors. All patients received oral ketoconazole or fluconazole and topical natamycin 5 percent, and intravitreal amphotericin B injections were also given in two patients. Four patients required a penetrating keratoplasty, enucleation was performed in two patients, two patients required a combination of a penetrating keratoplasty and pars plana vitrectomy, and one patient developed phthisis bulbi.

PAECILOMYCES LILACINUS

Paecilomyces lilacinus is an uncommon cause of exogenous endophthalmitis. However, this form of endophthalmitis has generally been associated with poor visual outcome. In a series of 13 cases of *Paecilomyces lilacinus* endophthalmitis following implantation of contaminated intraocular lenses, eight eyes were enucleated, two had a final vision of no light perception, and one had only light perception; retention of useful vision in the remaining two eyes was attributed to early removal of the lens and inflammatory material in one case and prompt use of intraocular miconazole in the other (Pettit et al. 1980). In another series of patients with postoperative *Paecilomyces lilacinus* endophthal-

mitis, enucleation was performed in two of the three cases; the salvaged eye was treated with miconazole early in the course of the disease (Kozarsky et al. 1984). In a case report of successful treatment of *Paecilomyces lilacinus* endophthalmitis following cataract extraction, treatment consisted of early vitrectomy, multiple intravitreal injections of amphotericin B and miconazole, intravenous miconazole, and later, oral ketoconazole; the intraocular lens removed 6 weeks after initiation of therapy was found to contain *Paecilomyces lilacinus*. After 8 months, excellent recovery of visual acuity was noted (Levin et al. 1987). Current management of ocular infections due to *Paecilomyces lilacinus* continues to be challenging because of the organism's resistance to amphotericin B, natamycin, and, in some cases, fluconazole (Aguilar et al. 1998; Sutton et al. 1998) and because miconazole and ketoconazole, agents to which *Paecilomyces lilacinus* is usually susceptible, are not usually included in the initial management of suspected fungal endophthalmitis (Scott et al. 2002). The sensitivity profile of *Paecilomyces lilacinus* also differs significantly from that of *Paecilomyces variotii* (Sutton et al. 1998). Therefore, initial treatment with miconazole (intravitreal, 25 μg/0.1 ml) has been suggested as a good option since, to date, miconazole is the only known medication to which *Paecilomyces lilacinus* and *Paecilomyces variotii* are consistently sensitive. Miconazole is currently available in powder form, which can be used to prepare topical and intravitreal preparations. If, however, miconazole is not readily available, a combination of intravitreal amphotericin B and oral ketoconazole (200–400 mg four times daily) has been suggested since *Paecilomyces variotii* is sensitive to amphotericin B and *Paecilomyces lilacinus* is sensitive to ketoconazole (Scott et al. 2002). However, while intravitreal amphotericin B is readily available from most pharmacies, ketoconazole is available only in an oral preparation. Intravitreal administration of fluconazole may be useful since approximately 10 percent of *Paecilomyces lilacinus* organisms are sensitive to fluconazole, which can be prepared in an intravitreal form. In the absence of miconazole, oral ketoconazole and intravitreal fluconazole may be considered (Scott et al. 2002).

PNEUMOCYSTIS CARINII

Patients with AIDS are at risk to develop pulmonary disease due to *Pneumocystis carinii*. Although aerosolized pentamidine may be given as prophylaxis in such patients, this does not protect against extrapulmonary disease. Dugel et al. (1990) and Foster et al. (1991) described the occurrence of choroidal lesions which appeared to be typical of *Pneumocystis carinii* in two and three patients, respectively, who were receiving prophylactic aerosolized pentamidine therapy. The lesions resolved with intravenous pentamidine therapy in four of the patients, while the lesions in the remaining patient resolved with intravenous trimethoprim and sulfamethoxazole. All these patients did not have clinical or laboratory evidence of *Pneumocystis carinii* infection other than in the eye. The choroidal lesions of *Pneumocystis carinii* manifest as yellow–white to orange spots without vitreous inflammation (Morinelli et al. 1993). Early ophthalmological examination may detect these lesions before they are threatening to sight, and allows systemic therapy to be instituted before widely disseminated infection due to *Pneumocystis carinii* results in a fatal outcome. Intravenous pentamidine therapy appears to control *Pneumocystis carinii* choroiditis but may need to be continued to prevent exacerbation. Presumed *Pneumocystis carinii* choroiditis may serve as a marker for disseminated infection.

FUNGAL OCULAR INFECTIONS AFTER OPHTHALMIC SURGICAL PROCEDURES

Certain surgical procedures are unique to ophthalmology. The most important ophthalmic surgical procedure is cataract extraction, and the most important fungal infection following cataract extraction is fungal endophthalmitis (see earlier under Intraocular mycoses). Fungal infections, such as keratitis and scleritis, have been reported following corneal refractive surgical procedures [radial keratotomy, photorefractive keratectomy, laser-in-situ keratomileusis (LASIK)], keratoplasty (corneal transplantation), pterygium excision, and cataract extraction.

Postoperative infectious keratitis is an uncommon, but serious, complication of radial keratotomy; the use of topical corticosteroids and the presence of corneal incisions are probably risk factors. There have been at least five reported cases of mycotic keratitis following radial keratotomy, two each due to species of *Fusarium* and *Aspergillus*, and one due to *Candida parapsilosis* (Maskin and Alfonso 1992; Gussler et al. 1995; Heidemann et al. 1995; Panda et al. 1998). Three of these responded to antifungals alone; the other two required therapeutic penetrating keratoplasty, wherein the lesions resolved.

Since LASIK combines the precision of excimer laser photoablation with the advantages of an intrastromal procedure that maintains the integrity of Bowman's layer and the overlying corneal epithelium, the risk of infectious keratitis following this procedure should be, theoretically speaking, minimal. However, microbial contamination of the corneal stromal bed may occur during surgery due to the proximity of the eyelids, eyelashes, conjunctiva, and microkeratome. This, combined with the use of topical corticosteroids, unstable epithelium at the edge of the lamellar flap, reduced corneal sensitivity and use of contact lenses, all render these eyes susceptible to infection. Read et al. (2000) reported the first case of mycotic keratitis due to *Acremonium atrogriseum* following LASIK; since then, there have been reports of at least five other patients afflicted with

this condition, in which six different species of fungi from five genera (*Aspergillus flavus*, *Aspergillus fumigatus*, *Curvularia* spp., *Fusarium solani*, *Scedosporium apiospermum*) have been implicated (Chung et al. 2000; Sridhar et al. 2000a, b; Kuo et al. 2001; Verma and Tuft 2002). Only two of these patients responded to medical therapy alone, and therapeutic penetrating keratoplasty was ultimately required for the other four. To achieve a favorable outcome in such infections, the fungus involved should first be identified as soon as possible; sampling at the site of infection (from underneath the flap) provides the best chance of obtaining a positive culture. This is followed by irrigation of the stromal bed with antifungal agents, and intensive treatment with specific systemic antifungals.

Mycotic keratitis has been reported to occur following superficial (lamellar) (Panda et al. 1999) or deep (penetrating) keratoplasty (Levenson et al. 1984; Wilhelmus and Robinson 1991; Ainbinder et al. 1998; Benaoudia et al. 1999), following repair of a dehiscent keratoplasty wound (Kisla et al. 2000), and secondary to endophthalmitis occurring after phacoemulsification and intraocular lens implantation surgery (Fekrat et al. 1995; Weissgold et al. 1998). The nine patients involved required surgery (therapeutic penetrating keratoplasty in seven, optical keratoplasty in one, and debridement in one). Four different yeast species (*Candida albicans*, *Candida guilliermondii*, *Candida parapsilosis*, and a *Rhodotorula* sp.) were isolated from the lesions of four patients, and four different species of filamentous fungi (*Exophiala dermatitidis* in two patients, *Acremonium kiliense*, *Beauveria bassiana*, and a presumed *Fusarium* sp. in one patient each) from the others.

Fungal scleritis has been reported to occur in at least 13 patients following various ophthalmic surgical procedures, including excision of pterygia (fleshy conjunctival growths) without or with β-irradiation (Margo et al. 1988; Moriarty et al. 1993; Sullivan et al. 1994; Kumar et al. 1997; Taravella et al. 1997), trabeculectomy (filtering surgery for glaucoma), and cataract extraction (Carlson et al. 1992; Bernauer et al. 1998; Locher et al. 1998). Various modalities of antifungal therapy, as well as surgical debridement, were not found useful in five of these 13 patients, with enucleation eventually having to be performed; *Scedosporium apiospermum* (*Pseudallescheria boydii*) was identified as the cause in two of these patients, *Scedosporium prolificans* in one, and an *Aspergillus* sp. in one. The identification of a *Rhizopus* sp. in the remaining patient is fraught with uncertainty since fungal hyphae were not visualized in the samples collected, and just one colony of the fungus was recovered in culture (Locher et al. 1998). Eight of 13 patients required some form of surgical intervention such as scleral debridement or resection, or removal of plaque, to ensure resolution of the infection; the fungi involved in these eight patients were *Aspergillus flavus* and *Aspergillus* spp. (in five patients), and *Scedosporium apiospermum*, *Scedosporium prolificans*, and a *Fusarium* sp. (in one patient each) (Carlson et al. 1992; Moriarty et al. 1993; Kumar et al. 1997; Bernauer et al. 1998).

Fungal infection of the self-sealing incision used for cataract surgery was reported in seven patients from different locales in India (Garg et al. 2003). The initial diagnoses at the time of onset of symptoms were keratitis, scleritis, and excessive anterior chamber reaction, but all cases subsequently developed deep keratitis. The diagnosis of fungal infection was established by microscopy and culture of corneal scrapings, corneoscleral biopsies, and anterior chamber aspirates, and the fungi isolated were species of *Aspergillus* in six patients and *Candida albicans* in one patient. The infection resolved with good visual recovery by medical therapy alone in two patients, but progressed to endophthalmitis and complete visual loss in five eyes.

OPHTHALMIC MYCOSES ASSOCIATED WITH AIDS

Infections by opportunistic microorganisms constitute an important ocular manifestation of AIDS, although ocular findings are infrequent in human immunodeficiency virus (HIV)-infected, asymptomatic individuals. Cytomegalovirus retinitis is reported to be the most common intraocular infection in AIDS patients while other opportunistic ocular infections are considerably less common (Jabs et al. 1989; Seal et al. 1998). Various types of ophthalmic mycoses, principally affecting the orbit and intraocular structures, have been reported in association with AIDS.

Frequency

Autopsy findings in 25 patients who died of AIDS revealed opportunistic ocular infections in eight patients, including retinitis due to a *Candida* spp. in one patient and choroiditis due to *Cryptococcus neoformans* var. *neoformans* in one patient (Jabs et al. 1989). Earlier, Schuman and Friedman (1983) had reported the occurrence of retinitis due to *Candida albicans* and *Cryptococcus neoformans* in two of 34 patients with AIDS; bacterial corneal ulceration was noted in 2 percent, but fungal corneal ulceration was not noted at all.

Orbital infections

Opportunistic infections of the orbit due to bacteria, fungi, and protozoa constitute serious complications of HIV infection and frequently lead to ocular morbidity and mortality. Orbital mycoses associated with AIDS have been reported in 15 patients since 1991 (Blatt et al. 1991; Friedberg et al. 1992; Vitale et al. 1992; Meyer et al. 1994; Kronish et al. 1996; Lee et al. 1996; Johnson et al. 1999; Hejny et al. 2001). The orbital mycotic infec-

tion resolved or improved in just six of these patients. Surprisingly, there was resolution or improvement following debridement and intravenous amphotericin B therapy in two of the three patients with rhino-orbital zygomycosis, perhaps because these had relatively focal lesions (Blatt et al. 1991; Hejny et al. 2001). There was complete resolution of lesions in the one patient with *Pneumocystis carinii* infection after treatment with trimethoprim and sulfamethoxazole (Friedberg et al. 1992). Eleven patients had infections due to *Aspergillus fumigatus*, and 10 of these were treated with surgery and intravenous amphotericin B. The patient survived and the mycotic infection resolved in only three of these patients who appeared to have relatively focal orbital lesions without intracranial disease; two of the survivors received surgery and amphotericin B (intravenous and local irrigation), while the third was treated by debridement, amphotericin B lipid complex, liposomal amphotericin B, and orbital exenteration (Vitale et al. 1992; Kronish et al. 1996; Johnson et al. 1999). Overall, it appears that orbital aspergillosis in patients with AIDS has a poor outcome.

Optic neuritis

Although there are many causes of optic neutritis in AIDS patients, a fungal etiology has been reported in two patients, the pathogen being *Histoplasma capsulatum* var. *capsulatum* (Specht et al. 1991; Yau et al. 1996); in one of these, the optic neuritis was associated with retinitis and uveitis.

Corneal infections

Fungal corneal infections appear to be infrequent in HIV-infected patients, but tend to be severe and prone to corneal perforation when they do occur and to manifest even when known risk factors for ulcerative keratitis are absent (Hemady 1995). There have been reports of six patients with mycotic keratitis associated with AIDS (in one patient, the diagnosis of AIDS was made postmortem); *Candida albicans* was the fungus implicated in all six patients (Parrish et al. 1987; Hemady 1995). The keratitis resolved in all six with topical amphotericin B (0.15 percent) therapy.

Other mycotic infections of the anterior segment reported in AIDS include limbal nodules (and multifocal choroiditis) in one patient (Muccioli et al. 1995) and an iris inflammatory mass in another (Charles et al. 1992); histopathological studies permitted a presumptive diagnosis of *Cryptococcus neformans* var. *neoformans* infection.

Presumed mycoses of the posterior segment in patients with AIDS include multifocal choroiditis (choroidopathy) and retinitis due to cryptococcosis, histoplasmosis, candidiasis, and *Pneumocystis carinii* infection (Macher et al. 1985; Jabs et al. 1989; Shami et al. 1991; Morinelli et al. 1993; Muccioli et al. 1995; Verma and Graham 1995). The choroidal lesions of *Pneumocystis carinii* manifest as yellow–white to orange spots without vitreous inflammation (Morinelli et al. 1993). Culture-proven endogenous endophthalmitis due to *Bipolaris hawaiiensis*, a *Fusarium* sp., *Sporothrix schenckii*, and *Histoplasma capsulatum* var. *capsulatum* has also been reported (Kurosawa et al. 1988; Pavan and Margo 1993; Glasgow et al. 1996; Gonzales et al. 2000); complete resolution of lesions was achieved by surgery and amphotericin B and fluconazole therapy only in the patient with the *Bipolaris* infection. Although central nervous system infection with *Cryptococcus neoformans* var. *neoformans* is common in patients with AIDS, actual invasion of the intraocular structures by the fungus appears relatively uncommon. In one study of 80 HIV-seropositive patients with cryptococcal infections, papilledema, visual loss, abducens nerve palsy, and optic atrophy were the important ophthalmic aberrations noted; however, actual invasion of the intraocular structures was an uncommon complication (Kestelyn et al. 1993).

OPHTHALMIC MYCOSES ASSOCIATED WITH OCULAR BIOMATERIALS

Microbial colonization of indwelling and implanted biomedical devices constructed of polymers, silicones, and metals, such as shunts or catheters, can lead to serious, often lethal, infection (Wilson 1996). The organisms responsible for such biomaterial-related infections are usually part of the resident microbial flora at a particular area of the body, therein posing a constant threat. Factors believed to contribute to the mechanisms of infection associated with biomedical devices include:

- intraoperative contamination during surgical implantation or extraluminal migration of organisms, which permits potential pathogens to transcend normal protective barriers
- production of mucoid substances by microorganisms, which facilitates adhesion of colonizing microorganisms, and also protects them from various host defense mechanisms
- the presence of plasma proteins (especially fibronectin) on the surface of the biopolymer, which may promote attachment of staphylococci and *Candida* spp. to the surface (Wilson 1996).

Contact lens plastics and their storage cases, and intraocular lens implants, are the two most important categories of biomaterials used in ophthalmology.

Fungal contamination of intraocular lenses

The occurrence of postoperative inflammation following implantation of an intraocular lens depends on various

factors, such as the type and surface quality of the lens, the fixation of the posterior chamber lens, the surgical technique adopted, the use of topical corticosteroids, systemic antibacterials, and nonsteroidal anti-inflammatory drugs as a prophylactic measure, as well as the experience of the surgeon. The use of polymethylmethacrylate single-block lenses in eyes with uveitis is advantageous since the complement cascade is not activated, while surface-modified lenses, such as heparin-coated models, may confer some protection against reactivation of inflammation (Biswas and Kumar 2002). Although improvements in the quality of the lenses and microsurgical techniques have led to a decrease in the frequency of complications from intraocular lenses, lenses that have been implanted intraocularly may still need to be explanted for various reasons. In a cytopathological study of five intraocular lenses that had to be removed due to endophthalmitis, fibrinous material was noted on three, granulomatous inflammation on one, and nongranulomatous inflammation with fungal filaments on the surface on one (Biswas and Kumar 2002); thus, careful examination of the intraocular lens surface in such cases would help in establishing a diagnosis of fungal endophthalmitis (Figure 18). In instances where the explantation of a contaminated intraocular lens is contraindicated, drug therapy may be the only alternative. Penk and Pittrow (1999) recently reviewed the role of fluconazole in the long-term suppression of fungal infections (mainly due to *Candida* spp.) in patients with artificial implants; their review included intraocular lenses in nine patients. These authors concluded that in such cases, fluconazole exhibited an excellent safety profile and therapeutic efficacy in doses of 750 mg/day; however, they cautioned that higher doses and lifelong treatment might be indicated in certain instances.

An outbreak of *Candida parapsilosis* endophthalmitis was reported in 13 patients from three states of the USA who had had an intraocular lens implantation between November 1983 and January 1984 (McCray et al. 1986). This outbreak was traced to the introduction in July 1983 of a new brand of BSS as an intraoperative ophthalmic irrigation solution that was subsequently recalled because of intrinsic fungal contamination. A retrospective cohort study revealed that definite exposure to the product was a significant risk factor for *Candida parapsilosis* endophthalmitis, while a retrospective case–control study, including 203 control patients with definite exposure to BSS, suggested that exposure to systemic steroids was an additional risk factor for this type of infection. All 13 patients received topical, intraocular, or systemic antifungal therapy (or a combination of these modalities), and 10 also underwent vitrectomy. No patients had systemic symptoms or complete visual loss. Laboratory investigations showed a 6.7 percent overall contamination of the product with *Candida parapsilosis*. The problem did not recur following recall of the product by the manufacturer.

Thirteen cases of fungal endophthalmitis caused by *Paecilomyces lilacinus* were attributed to implantation of intraocular lenses that had been sterilized in sodium hydroxide and neutralized in sodium bicarbonate (Pettit et al. 1980). Twelve of the 13 patients had received neutralizing solution from one particular lot, and the same fungus that caused the endophthalmitis was cultured from several of the neutralizing solutions from this particular lot. Eight of the 13 eyes eventually required enucleation. Of the remaining five eyes, only two recovered useful vision. This surgically induced epidemic of fungal endophthalmitis clearly shows the major consequences of a breakdown in quality control for any substance or material used intraocularly. Tabbara and al-Jabarti (1998) reported on the occurrence of exogenous endophthalmitis due to *Aspergillus fumigatus* in five patients who had undergone extracapsular cataract surgery with posterior chamber intraocular lens implantation. In these patients, however, the intraocular lens was not at fault but, rather, ongoing hospital construction work.

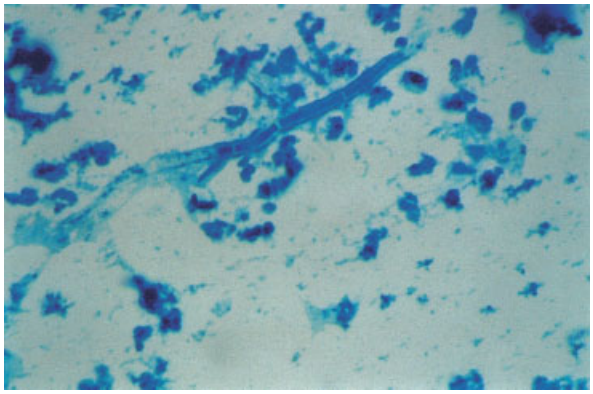

Figure 18 *Photomicrograph of fungal hyphae (*Aspergillus fumigatus*) on an intraocular lens that was removed due to endophthalmitis. Lactophenol cotton blue stain; magnification ×400*

Fungal contamination of contact lenses

Contact lens-associated mycotic keratitis appears to be relatively uncommon, when compared to contact lens-associated bacterial or *Acanthamoeba* keratitis, because fungi isolated from the healthy outer eye only transiently colonize this area, and are not normally resident in the outer eye (Srinivasan et al. 1991; Liesegang 1997). When soft lenses are worn continuously, fungal conidia adhere to the lens surface and, under favorable conditions, germinate; fungal hyphae are able to enter the matrix of the soft lens, project through the posterior surface and then penetrate the corneal epithelium, resulting in fungal infection (Simmons et al. 1986). Factors that possibly contribute to such infiltration

include fungal enzymatic activity and properties of the lens material, which provide a matrix as well as a source of nutrients for growth of the fungi (Yamamoto et al. 1979). Fungi have been found to penetrate the matrix of extended-wear soft contact lenses, both during normal use (Yamamoto et al. 1979; Berger and Streeten 1981; Wilson and Ahearn 1986) and in laboratory studies (Yamaguchi et al. 1984). When contact lenses with a water content of 45 or 73.5 percent were challenged with *Fusarium solani* or *Aspergillus flavus* on Sabouraud glucose neopeptone agar, it was found that the fungi penetrated both lenses but appeared to grow more vigorously into the lenses with the higher water content, resulting in physical and metabolic degradation of these lenses (Yamaguchi et al. 1984). In another study, it was thought that contamination of 11 extended-wear soft contact lenses by fungi occurred while the lenses were on the eye (Wilson and Ahearn 1986); in two cases, the same fungi isolated from the contaminated lenses were also obtained from corneal ulcers immediately underlying the fungal contamination on the soft lens. Simmons et al. (1986) reported that filamentous fungi of the genera *Acremonium*, *Aspergillus*, *Alternaria*, *Cladosporium*, *Curvularia*, and *Fusarium* penetrated the matrix of soft contact lenses during normal use and in laboratory studies. The species of *Acremonium*, *Aspergillus*, and *Fusarium* readily penetrated lenses having a water content of 55 percent or greater following incubation for 120–168 hours; when germinating on lenses, the conidia of these fungi appeared to be often associated with small salt deposits. Dematiaceous fungi appeared to penetrate intraocular lenses very rapidly. Conidia of *Cladosporium cladosporioides* were found to germinate on a new 55 percent water-content lens, either producing flattened appressorium-like cells on the lens surface or penetrating the lens with a finely coiled and tapered hyphal element within the first 12 hours of incubation; conidia of *Curvularia lunata* were found to germinate and penetrate into and through a new 55 percent water-content lens within 96 hours. Some hyphae adhered primarily to ridges or crevices or occasionally to small salt deposits on the lenses, but adherence to smooth surfaces was also observed. Growth of the fungal hyphae (which were coiled within the lens matrix) increased with increasing water content of the lens (Simmons et al. 1986). Based on these findings, these authors agreed with the general recommendation that lenses with fungal deposits be replaced, and also advised frequent and regular cleaning and disinfection of extended-wear lenses. They also suggested that activities in moldy habitats, such as raking leaves, cleaning dusty areas, and showering in rooms with moldy plastic curtains or tiles, be completely avoided while wearing extended-wear lenses, or that the lenses be cleaned and disinfected after such activities.

If fungal conidia alight on the surface of a contact lens, they are normally removed by surface cleaning of the lens. If such lenses are worn without proper cleaning for an extended duration, fungi may adhere, and penetrate the contact lens (Wilson 1996). This may explain why soft lenses for aphakia and therapeutic extended wear have been most frequently implicated in such infections (Wilson and Ahearn 1986; Starr 1987; Wilhelmus et al. 1988).

Fungal infection was reported in four (4 percent) of 90 contact lens wearers, and in four (27 percent) of patients who wore therapeutic bandage-contact lenses (Wilhelmus et al. 1988). Filamentous fungi (*Aspergillus flavus*, *Fusarium dimerum*, *Fusarium* sp.) were also reported to have been isolated from the corneal scrapes of several other patients in South Florida who had contact lens-associated fungal keratitis (Liesegang and Forster 1980; Alfonso et al. 1986). Interestingly, Wilhelmus et al. (1988) observed that filamentous fungi are more likely to be associated with keratitis in persons wearing cosmetic or aphakic lenses, whereas yeasts were more frequently found with therapeutic lens use. Rosa et al. (1994) reported that six of their 125 patients with mycotic keratitis in south Florida wore extended-wear contact lenses; *Fusarium oxysporum* was isolated from four patients and *Candida albicans* and a *Paecilomyces* sp. from one patient each. In one patient who wore a bandage contact lens, keratitis due to *Candida parapsilosis* developed. Liesegang and Forster (1980) had earlier reported the occurrence of fungal keratitis in three patients who wore soft contact lenses, the fungi isolated being *Aspergillus flavus* and *Fusarium dimerum*. *Candida parapsilosis* keratitis, associated with contact lens wear, was reported in an elderly Israeli patient who developed stromal infiltration at the donor/recipient interface 2 years after penetrating keratoplasty, while wearing a 'piggyback' type of contact lens; the infection resolved with amphotericin B and flucytosine (Kremer et al. 1991). Perry et al. (1998) reported the occurrence of a conjunctival mass and keratoconjunctivitis in an immunocompetent patient; detailed examination revealed the presence of a soft contact lens, covered by mucoid material, at the posterior aspect of this mass, and the simple removal of the lens resulted in a resolution of all signs and symptoms, with the contact lens growing *Aspergillus fumigatus*. Keratouveitis associated with the intraocular long-term retention of a contact lens was reported in a 76-year-old female patient (Arthur et al. 2001); a fungus was found to be involved, and this was identified as *Scedosporium prolificans*. However, this identification was found to be erroneous, and the isolate was later reidentified as *Acrophialophora fusispora* (Guarro and Gené 2002).

While the occurrence of contact lens-associated bacterial and *Acanthamoeba* keratitis has been correlated with the presence of bacteria and *Acanthamoeba* in contact lens cases (Seal et al. 1992; McLaughlin-Borlace et al. 1998), it is unclear whether such a relationship occurs in contact lens-associated fungal keratitis. However, Wilson et al. (1991) demonstrated the

adherence of *Candida albicans* within a biofilm to polyethylene contact lens case plastic; this was found to be more resistant to the action of contact lens disinfectants than bacteria. A survey of contact lens cases from 101 asymptomatic daily-wear, cosmetic contact lens wearers in a domiciliary contact lens practice revealed contamination in 82 (81 percent) cases; 77 percent grew bacteria, 24 percent fungi, and 20 percent protozoa (Gray et al. 1995). Keratitis due to *Cryptococcus laurentii* and *Fusarium solani* was recently reported in a diabetic male patient who wore a gas-permeable contact lens (Ritterband et al. 1998); both fungi were isolated from the patient's corneal button, infected toe nails, and contact lens storage case, and enucleation eventually had to be performed.

Overnight soaking of soft lenses in 3 percent hydrogen peroxide (longer than 4 hours), with neutralization in the morning by thiosulfate solution, catalase solution, or catalase tablets is perhaps the safest way to ensure killing of bacteria, *Acanthamoeba*, and fungi (Chandler 1990; Wilson 1996). However, in one study, as many as 75 percent of individuals who used hydrogen peroxide disinfection for their contact lenses were found to have contact lens cases that were contaminated with microbes (Gray et al. 1995); all the contaminating microorganisms were found to possess the enzyme catalase (which breaks down hydrogen peroxide to water and oxygen). Recommendations for contact lens wearers to prevent microbial contamination of the lens and case include regular scrubbing of the interior of contact lens cases to disrupt biofilms, exposure of the contact lens case to very hot water ($\geqslant$70°C), air-drying of the contact lens case between use, use of a two-step system for hydrogen peroxide disinfection, and regular replacement of the contact lens case (Gray et al. 1995; Seal et al. 1998).

Fungal contamination of other ocular biomaterials

Punctal occluders or plugs aid the management of dry eye syndrome. However, since these devices are left in situ for a long duration, nonspecific microbial attachment, surface colonization, and biofilm formation may occur. Fungi such as *Curvularia lunata* may sometimes be implicated (Wilson 1996).

Several alloplastic biomaterials have been used for repair of the orbital floor and to restore an anophthalmic socket. Oestreicher et al. (1999) described a patient who developed an *Aspergillus* abscess within a hydroxyapatite orbital implant 58 months following uncomplicated implant surgery; the symptoms resolved following removal of the implant.

Patients with corneal or scleral defects have been treated with Gore-Tex grafting; Huang et al. (1994) reported the occurrence of fungal contamination in one such graft, which ultimately led some months after graft removal to fungal endophthalmitis and penetrating keratoplasty.

ACKNOWLEDGMENTS

The authors are grateful to J. Kaliamurthy, C.M. Kalavathy, D. Arvind Prasanth, A. Geetha, R.T. Rajagowthamee, and P. Archana Teresa for their abundant help, and to C.A. Nelson Jesudasan for permitting them to utilize the patient and laboratory records and other facilities available at the Institute of Ophthalmology, Joseph Eye Hospital, Tiruchirapalli, in the preparation of this chapter.

Subcutaneous zygomycosis

DAVID H. ELLIS

Etiologic agents of medical importance	1	Treatment (management/therapy)	6
Host responses	4	References	6
Laboratory diagnosis	5		

The Entomophthorales are a group of primitive fungi belonging to the Zygomycetes, with infrequently septate (coenocytic) hyphae in which the sporangium has been reduced to function as a single conidium that is forcibly discharged at maturity. If the conidium does not land on a favorable substrate, it in turn produces a second and smaller conidium, which is again shot away. This cycle may be repeated several times. Members of the Entomophthorales are often parasitic on insects, and other animals and some species have developed very potent proteolytic enzyme systems. Although they are capable of growing saprobically in pure culture, many species require a complex nutrient medium to stimulate sporulation (King 1983). Currently the Entomophthorales are classified into six families with 22 genera containing some 132 species (Humber 1989). However, the order may be heterogeneous as recent molecular data has shown *Basidiobolus* to cluster with some of the Chytridiales, and *Conidiobolus*, *Entomophthora*, and *Zoopthora* with the Mucorales (Nagahama et al. 1995).

Basidiobolus ranarum (*Basidiobolaceae*), *Conidiobolus coronatus* (*Ancylistaceae*), and *Conidiobolus incongruus* are the only species that are known to cause human disease (Table 1). *Conidiobolus lamprauges* has also been reported once from a horse (Humber et al. 1989). Infections caused by *B. ranarum* usually present as chronic, painless, indurated subcutaneous masses and have been referred to by a variety of names, such as basidiobolomycosis (Kwon-Chung and Bennett 1992), entomophthoramycosis basidiobolae (Emmons et al. 1977), and subcutaneous zygomycosis (Rippon 1988; Goodman and Rinaldi 1991). *C. coronatus* infections usually occur as chronic granulomatous lesions of the nasal mucosa, often spreading to the contiguous facial skin and have also been called a variety of names, such as conidiobolomycosis, entomophthoramycosis conidiobolae, and rhinoentomophthoromycosis (Emmons et al. 1977; Kwon-Chung and Bennett 1992).

The term 'zygomycosis' has often been used to describe in the broadest sense any infection caused by a member of the Zygomycetes. However, many authors still prefer to use the term 'mucormycosis' to describe mycoses caused by members of the Mucorales and entomophthoromycosis (or entomophthoramycosis – the spelling used seems to depend upon the author) to describe mycoses caused by species belonging to the Entomophthorales. In general, fungi in the order Mucorales cause the more severe forms of disease (see

Systemic zygomycosis), whereas those in the order Entomophthorales cause a more chronic disease of the nasal mucosa and subcutaneous tissue (Goodman and Rinaldi 1991).

ETIOLOGIC AGENTS OF MEDICAL IMPORTANCE

Basidiobolus ranarum Eidem

The genus *Basidiobolus* is distinguished primarily by the morphology and development of forcibly discharged conidia and 'beaked' zygospores, both of which must be observed for reliable identification to genus and species level (King 1983). As all species of *Basidiobolus* lose their ability to sporulate after being maintained in culture for a relatively short time, it is very important to examine freshly isolated strains as soon as possible (Drechsler 1955; King 1979, 1983). This lack of

Table 1 *Families and genera of the Entomophthorales of medical importance*

Family	Genus	Key identification features
Ancylistaceae	*Conidiobolus*	Sporophores without subsporangial vesicle; nucleus difficult to observe during mitosis; nucleolus prominent Forcibly discharged multireplicative conidia with prominent papillae and villi
Basidiobolaceae	*Basidiobolus*	Sporophores with subsporangial vesicle; all cells uninucleate Forcibly discharged conidia and zygospore morphology

sporulation in culture, combined with other unsatisfactory criteria for separating the species, such as optimum growth temperature, *Streptomyces*-like odor, and zygospore wall undulation, has led to some confusion in the identification of the pathogenic isolates (Hutchison et al. 1972). In the past, pathogenic isolates have been classified as *B. ranarum* (Emmons et al. 1977), *Basidiobolus meristosporus* (Drechsler 1956; Greer and Friedman 1966; Clark 1968; Coremans-Pelseneer 1973), and *Basidiobolus haptosporus* (Srinivasan and Thirumalachar 1965, 1967; Miller and Pott 1980; Miller and Turnwald 1984). However, recent advances in taxonomy, including antigenic studies (Yangco et al. 1986), restriction analysis of rDNA (Nelson 1989), and isoenzyme banding (Cochrane et al. 1989), indicate that all human pathogenic isolates of *Basidiobolus* belong to *B. ranarum* (McGinnis 1980b; Kwon-Chung and Bennett 1992). *B. ranarum* is also known to produce extracellular protease and lipase, which can be detected in agar media (Okafor et al. 1987).

B. ranarum is commonly present as a saprophyte in soil, decaying fruit and vegetable matter, and in the dung of amphibians and reptiles. The animals show no intestinal lesions (Clark 1968; Nickerson and Hutchinson 1971; Tills 1977; Gugnani and Okafor 1980; Okafor et al. 1984; Zahari and Shipton 1988; Nelson et al. 2002), although cutaneous lesions have been reported in amphibians (Groff et al. 1991; Taylor et al. 1999). Less commonly, it has been recovered from the intestinal tract of insectivorous bats, the dung of macropod species, and from wood lice (Chaturvedi et al. 1984; Speare and Thomas 1985; Zahari and Shipton 1988). Subcutaneous infections have been well documented in horses (Miller and Pott 1980; Miller and Campbell 1982, 1984; Miller 1985), dogs (Greene et al. 2002), and in humans (Joe and Njo-Imjo 1956; Dasgupta et al. 1976; Mugerwa 1976; Bittencourt et al. 1979, 1991; Davis et al. 1994); gastrointestinal lesions have also been noted in dogs (Miller 1985), and with increasing occurrence in humans (de Agular et al. 1980; Schmidt et al. 1986; Yousef et al. 1999; Khan et al. 2001; Lyon et al. 2001). *B. ranarum* has been reported from tropical Africa, India, Indonesia, and southeast Asia, including northern Australia (Zahari et al. 1990), with human infections being limited to the warmer regions of the world (King 1979, 1983; Gugnani 1999).

Colonies of *B. ranarum* are moderately fast growing at 30°C, flat, yellowish-gray to creamy-gray, glabrous, becoming radially folded and covered by a fine, powdery, white surface mycelium. Note that conidia ejected from the primary colony often germinate to form satellite colonies. Microscopic examination usually shows the presence of large vegetative hyphae (8–20 μm in diameter) forming numerous round (20–50 μm in diameter), smooth, thick-walled zygospores that have two closely appressed beak-like appendages (Figure 1). The production of 'beaked' zygospores is diagnostic for the genus. Two types of asexual conidia are formed: primary and secondary. Primary conidia are globose, one celled, solitary, and forcibly discharged from a sporophore. The sporophore has a distinct swollen area just below the spore, which actively participates in the discharge of the spore (Figure 1). Secondary (replicative) conidia are clavate, one celled, and passively

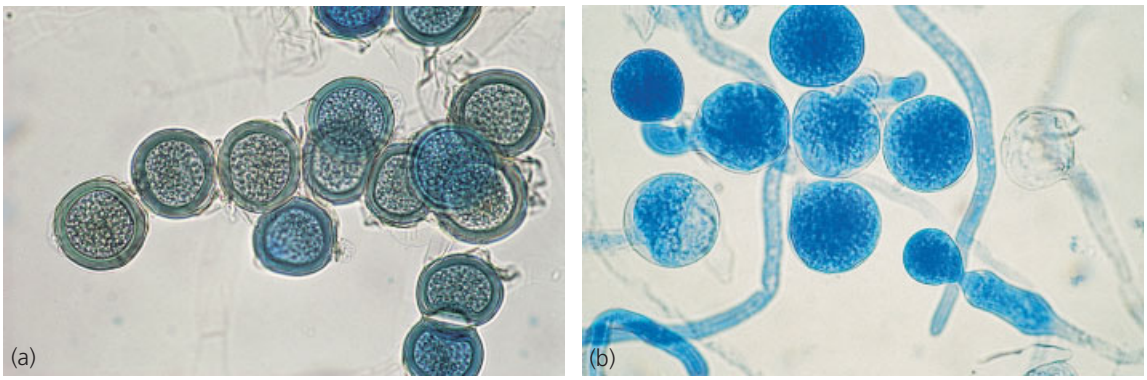

Figure 1 Basidiobolus ranarum*:* **(a)** *zygospores;* **(b)** *conidia and sporophores. Magnification ×495.*

released from a sporophore. These sporophores are not swollen at their bases. The apex of the passively released spore has a knob-like adhesive tip. These spores may function as sporangia, producing several sporangiospores. Note that isolates often lose their sporulating ability with subculture and special media, incorporating glucosamine hydrochloride and casein hydrolysate, may need to be used to stimulate sporulation (Shipton and Zahari 1987). Key features include forcibly discharged conidia and the presence of smooth-walled zygospores with prominent beak-like appendages. (For additional information, see Srinivasan and Thirumalachar 1965, 1967; Greer and Friedman 1966; Dworzack et al. 1978; McGinnis 1980a; King 1983; Rippon 1988; Drouhet and Ravisse 1993; Jong and Dugan 2003.)

Conidiobolus species

The species of the genus *Conidiobolus* produce characteristic multinucleate primary and secondary (replicative) conidia on top of unbranched conidiophores. Each subspherical conidium is discharged as a result of the pressure developed within the conidium, and each bears a more or less prominent papilla after discharge (King 1983). The genus contains 27 species; it has recently undergone taxonomic revision and is now classified in the family *Ancylistaceae* (see King 1976a, b, 1977, 1979; Humber 1989). However, isolates of *C. coronatus* and *C. incongruus* are the only species that are known to cause human disease, although *C. lamprauges* has also been reported once from a horse (Humber et al. 1989). Isolates of the *Conidiobolus* species do not tend to lose the ability to sporulate as readily as isolates of *B. ranarum*. Most strains of *C. coronatus* readily produce villous conidia.

CONIDIOBOLUS CORONATUS (COSTANTIN) BATKO

C. coronatus, synonym *Entomophthora coronata* (Costantin) Kevorkian, has a worldwide, mainly tropical distribution and is commonly present as a saprophyte in soil and on decaying vegetation (King 1983). It has been most frequently isolated in the tropical rain forests of Africa (Fromentin and Ravisse 1977). It is an occasional pathogen of insects worldwide, and has been isolated from dolphins (Sweeney and Migaki 1976), chimpanzees (Roy and Cameron 1972), sheep (Carrigan et al. 1992; Ketterer et al. 1992), llama (Moll et al. 1992; French and Ashworth 1994), and from horses as far north as southern Texas (Emmons and Bridges 1961; French et al. 1985) and as far south as Australia (Hutchins and Johnson 1972; Miller and Campbell 1982). Human infections are usually restricted to the rhinofacial area (Rippon 1988; Costa et al. 1991; Ng et al. 1991; Gugnani 1992; Kwon-Chung and Bennett 1992). However, there are occasional reports of dissemination to other sites (Rinaldi 1989; Jaffey et al. 1990; Walker et al. 1992). All human infections have been confined to the tropics (King 1983).

There has been much confusion as to the correct name of this species, and it is often listed under an older synonym *Delacoixia coronata* (Cost.) Sacc. & P. Syd. (de Hoog and Guarro 1995). This has been further compounded by recent investigations of sterol content, which suggest separation of *C. coronatus* (as *Delacoixia coronata*) from other fungi in *Entomophthora*, *Basidiobolus*, and *Conidiobolus* (Weete and Gandhi 1997). However, the name *C. coronatus* is now generally accepted and is retained for the purposes of this chapter. With the possible exception of a few human isolates, all strains of *C. coronatus* produce villous conidia, and about 75 percent of the strains isolated from plant debris produce multireplicative conidia (King 1976a, 1979, 1983). Some strains also produce abundant spherical chlamydoconidia submerged in the agar, but zygospores are not known to be formed by this species (King 1983).

Colonies grow rapidly and are flat, cream colored, glabrous, becoming radially folded and covered by a fine, powdery, white surface mycelium and conidiophores. The lid of the Petri dish soon becomes covered with conidia that were forcibly discharged by the conidiophores. The color of the colony may become tan to brown with age. Conidiophores are simple, forming solitary, terminal conidia, which are spherical, 25–45 μm in diameter, multinucleate, single celled, and have a prominent papilla (Figure 2). Conidia may also produce hair-like appendages called villi. Conidia germinate to produce either:

- single or multiple hyphal tubes which may also become conidiophores that bear secondary conidia, or
- multiple short conidiophores, each bearing a small secondary conidium.

Key features include forcibly discharged conidia with conspicuous basal papillae and villous hair-like projections that readily distinguish *C. coronatus* from other species. (For additional information see Emmons and Bridges 1961; King 1976a, 1983; McGinnis 1980a; Rippon 1988; Kwon-Chung and Bennett 1992; de Hoog et al. 2000.)

CONIDIOBOLUS INCONGRUUS DRECHSLER

C. incongruus is only rarely isolated as a saprophyte from plant debris or as a pathogen causing human or animal infection. Animal infections have been reported once from a deer (Stephens and Gibson 1997) and from five cases of rhinocerebral and nasal zygomycosis in sheep (Ketterer et al. 1992). Human infections are also infrequent. The first case report was of a 15-month-old boy with indolent pneumonia, mediastinitis, and pericarditis who was successfully treated with amphotericin B (Gilbert et al. 1970; Eckert et al. 1972; King and Jong 1976). A fatal disseminated infection was then reported by Busapakum et al. (1983). Since then a case of

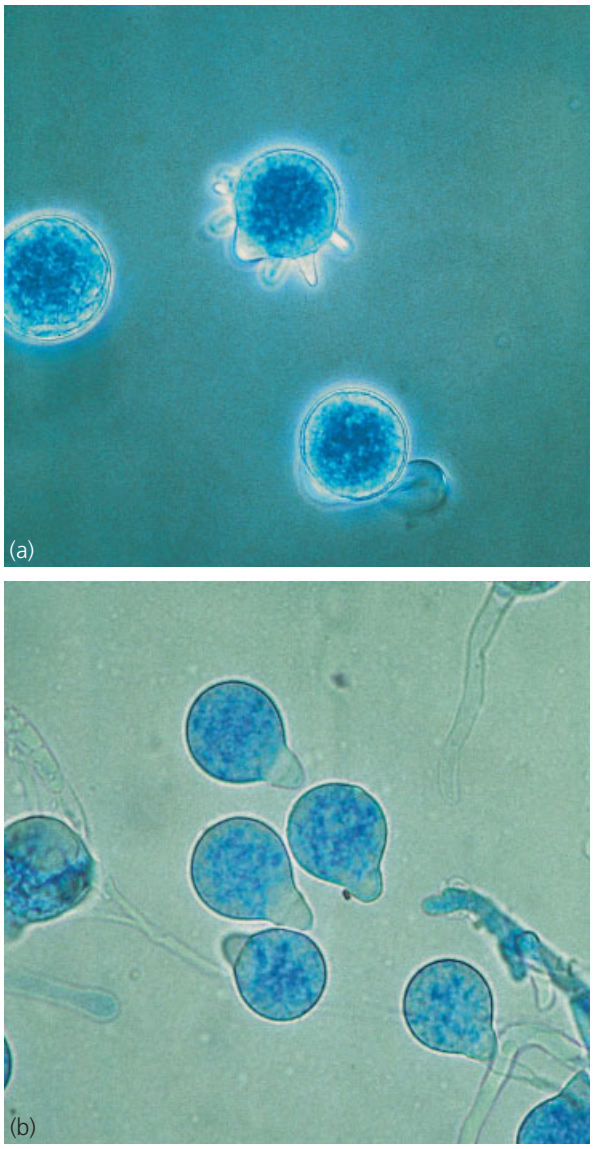

Figure 2 Coniodobolus coronatus: **(a, b)** *spherical conidia with hair-like appendages (villi) and prominent papillae. Magnification ×495.*

endocarditis in a cocaine abuser (Jaffey et al. 1990), a fatal disseminated case in a renal transplant patient (Walker et al. 1992), and an orbitofascial infection in a child (al-Hajjar et al. 1996) have also been reported. Another recent human case report described a granulocytic patient with pulmonary and pericardial infection and concluded that *C. incongruus* was an uncommon but highly invasive fungal pathogen that may be resistant to amphotericin B (Walsh et al. 1994). Colony characteristics are similar to *C. coronatus* and are flat, white becoming brown with age, and glabrous becoming radially folded with minimal surface mycelium. Zygospores are yellowish, spherical to elongate (15–25 μm in diameter), thick walled and without beaks. Primary conidia are forcibly discharged, spherical to pyriform (11–37×12–42 μm in diameter) with a tapering, often sharply pointed, basal papilla. Zygospores and multiplicative conidia must be observed to identify *C. incongruus*. Key features include forcibly discharged conidia with pronounced elongated basal papilla but without the hair-like villous projections that distinguish this species from *C. coronatus*. (For additional information, see King and Jong 1976; King 1977, 1979, 1983; Busapakum et al. 1983; Rippon 1988; Kwon-Chung and Bennett 1992.)

CONIDIOBOLUS LAMPRAUGES DRECHSLER

C. lamprauges is also rare, having been isolated from plant debris and occasionally from insects, and from a granulomatous nasopharyngeal nodule of a horse (Humber et al. 1989). No human infections have been reported. *C. lamprauges*, like *C. coronatus*, produces zygospores but not villose conidia. Colony characteristics are similar to *C. coronatus* and are flat, whitish becoming radially folded with minimal surface mycelium. Zygospores are spherical (12–18 μm in diameter), thick walled and with two protruding lateral appendages or beaks. Conidiophores are hypha-like, irregular, and are not swollen at their apices. Primary conidia are forcibly discharged, densely granular when immature, spherical (13–22 μm in diameter), thin walled, with one to several flat papilla after liberation. Key features include zygospores with two 'beaks,' forcibly discharged conidia with one or more papilla but without the hair-like villous projections that also distinguish this species from *C. coronatus*. (For additional information, see Kwon-Chung and Bennett 1992; de Hoog et al. 2000; Jong and Dugan 2003.)

HOST RESPONSES

Infections caused by entomophthoraceous fungi result from species of 2 genera: *Basidiobolus* and *Conidiobolus*. Infections are chronic, slowly progressive, and generally restricted to the subcutaneous tissue in otherwise healthy individuals. Other characteristics that separate these infections from those caused by mucoraceous fungi are a lack of vascular invasion or infarction and the production of a prolific chronic inflammatory response, often with eosinophils and the Splendore–Hoeppli phenomenon around the hyphae (Kwon-Chung and Bennett 1992).

Entomophthoromycosis caused by *B. ranarum* is a chronic inflammatory or granulomatous disease generally restricted to the subcutaneous tissue of the limbs, chest, back, or buttocks, primarily occurring in children and with a predominance in males (Martinson 1972; Clark 1975; Bittencourt et al. 1979; Rippon 1988; Rinaldi 1989; Kwon-Chung and Bennett 1992; Gugnani 1999). Initially, lesions appear as subcutaneous nodules which develop into massive, firm, indurated, painless swellings which are freely movable over the underlying muscle, but attached to the skin, and which may become hyperpigmented although not ulcerated (Kwon-Chung and

Bennett 1992). The first human case caused by *B. ranarum* was reported in 1956 in Indonesia (Joe and Njo-Imjo 1956) and subsequently cases have been reported in India (Dasgupta et al. 1976), Africa (Mugerwa 1976), South America (Bittencourt et al. 1979), and northern Australia (Davis et al. 1994). The first culture-proven invasive infection by *B. ranarum* (syn. *B. haptosporus*) was reported in the USA (Dworzack et al. 1978). This was an unusual case, with a description of an ulcerative lesion perforating the hard palate of an adult patient. Gastrointestinal infection appears to be an emerging entity (de Agular et al. 1980; Schmidt et al. 1986; Yousef et al. 1999; Khan et al. 2001; Lyon et al. 2001) and poses several diagnostic difficulties. Its clinical presentation is nonspecific, there are no identifiable risk factors, and all age groups are susceptible; as a result many cases have been confused with Crohn's disease (Zavasky et al. 1999). A case of muscle invasion by *B. ranarum* resulting from deep penetration of this fungus has also been described (Kamalam and Thambiah 1984). *B. ranarum* most probably gains entrance to human tissue following traumatic implantation by insect bites, scratches, and minor trauma (Kwon-Chung and Bennett 1992). This may also explain why it is most commonly encountered in children, involving the thighs or buttocks.

Entomophthoromycosis caused by *Conidiobolus* spp. is a chronic inflammatory or granulomatous disease, which is typically restricted to the nasal submucosa and characterized by polyps or palpable restricted subcutaneous masses (Martinson 1972; Herstoff et al. 1978; Winter and Carme 1984; Rippon 1988). Clinical variants, including pulmonary and systemic infections, have also been described (Busapakum et al. 1983). Human infections occur mainly in adults with a predominance in males (80 percent of cases). Most cases have been reported from the tropical rainforest areas of central and west Africa (Okafor et al. 1983; Winter and Carme 1984) and South and Central America (Rippon 1988). Infections usually begin with unilateral involvement of the nasal mucosa. Symptoms include nasal obstruction, drainage, and sinus pain. Subcutaneous nodules develop in the nasal and perinasal regions and progressive generalized facial swelling may occur (Richardson and Warnock 1993). Infections also occur in horses, usually producing extensive nasal polyps (Emmons and Bridges 1961; Miller and Campbell 1982; Miller 1983; French et al. 1985), and other animals (Miller 1985). *C. coronatus* is also a recognized pathogen of termites, other insects, and spiders (King 1979). *Conidiobolus* infections are believed to occur following inhalation of conidia and subsequent tissue invasion of traumatized nasal mucosa (Kwon-Chung and Bennett 1992).

LABORATORY DIAGNOSIS

A tissue biopsy is essential, and swabs are not recommended. Tissue samples should be kept moist with saline or brain–heart infusion broth and be transported to the laboratory as soon as possible. It is essential that both direct microscopy and culture be performed on all specimens. It should also be noted that zygomycetous fungi have coenocytic hyphae, which will often be damaged and become nonviable during the biopsy procedure or by the chopping up or tissue grinding processes in the laboratory. This is why zygomycetous fungi that are clearly visible in direct microscopic or histopathological mounts are often difficult to grow in culture from clinical specimens. Therefore it is important to avoid excessive tissue damage when collecting the specimen and in the laboratory to gently tease the tissue apart and inoculate it directly onto the isolation media.

Direct microscopy and histopathology

Histopathology is the most rapid diagnostic method and the presence in clinical specimens of broad, 5–15 μm wide, infrequently septate, thin-walled hyphae that are surrounded by an eosinophilic sheath, known as the Splendore–Hoeppli phenomenon, is characteristic (Figure 3). There are two major histological differences between subcutaneous zygomycosis caused by *Basidiobolus* and *Conidiobolus* (entomophthoromycosis) and zygomycosis caused by members of the Mucorales (mucormycosis). First, in entomophthoromycosis, an eosinophilic sheath surrounds the hyphae and there is a lack of vascular invasion, which is so characteristic of infections caused by the Mucorales. Second, the hyphal elements of Mucorales are sparsely septate in tissue, whereas frequent septation is seen in tissue hyphae of *Basidiobolus* or *Conidiobolus*. Direct microscopy of biopsy tissue may be performed using 10 percent KOH ink or calcofluor mounts. A small piece of tissue may be mounted in KOH on a glass slide, teased apart, and gently heated to dissolve the tissue prior to microscopic

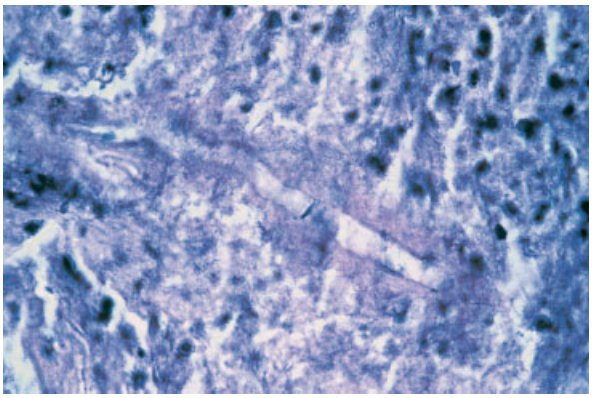

Figure 3 *Tissue morphology in entomophthoromycosis: H&E stained section of infected tissue showing broad, infrequently septate, hyphae surrounded by an eosinophilic sheath (Splenodore–Hoeppli phenomenon), typical of* Basidiobolus ranarum.

examination for the presence of zygomycetous hyphae. Tissue sections should be stained with hematoxylin and eosin (H&E), periodic acid–Schiff (PAS), and Gomori's methenamine silver (GMS) (Grocott 1955) stains. H&E-stained tissue sections are best to observe the distinctive eosinophilic sheath (Splendore–Hoeppli phenomenon) that typically surrounds the hyphae. However, GMS-stained sections are still necessary as often the hyphae stain poorly (Chandler et al. 1980; Rippon 1988; Salfelder 1990).

Culture

Biopsy tissue should be inoculated onto culture media without delay; it should not be kept for an extended time in a refrigerator (Burkitt et al. 1964). Sabouraud's dextrose agar containing antibacterial antibiotics, but without cycloheximide (actidione), is usually used as the primary isolation medium. Strains of *Basidiobolus* also rapidly lose their ability to sporulate after relatively short periods of time in culture. This problem has been partially overcome by the use of media that incorporate glucosamine hydrochloride and casein hydrolysate (Shipton and Zahari 1987). Nevertheless, isolates should be examined and preserved in liquid nitrogen as quickly as possible after isolation (Jong and Dugan 2003). Most isolates of *Basidiobolus* and *Conidiobolus* are fast growing, 2–5 days at 26–28°C, initially whitish, later becoming buff or gray, with a glabrous to waxy or powdery radiate surface. For isolation from environmental sources such as soil, decaying leaves, or the intestinal contents of reptiles, specimens can be shaken in sterile water and the supernatant then pipetted onto a sterile Whatman no. 1 filter paper. The filter paper is then placed on the inside of a petri dish lid covering an agar plate. The petri dish is then incubated upside down to allow the forcible discharged conidia to land on the agar surface. Colonies take about 3 days to appear in positive samples (Rippon 1988).

Immunology and serology

Serological testing for antibodies by immunodiffusion against both *Basidiobolus* and *Conidiobolus* spp. has been developed (Kaufman et al. 1990; Imwidthaya and Srimuang 1992) and has been used on a limited basis for diagnostic purposes, especially when the culture result is negative (Lyon et al. 2001). Exoantigen tests have also been developed for the identification of cultures by immunodiffusion (Yangco et al. 1986; Toriello et al. 1989).

TREATMENT (MANAGEMENT/THERAPY)

In subcutaneous infections caused by *B. ranarum*, the therapy of choice still appears to be saturated potassium iodide solution. The usual dose has been about 30 mg/kg/day, given either as a single dose or divided into three daily doses, which should be given for 6–12 months (Koshi et al. 1972; Mugerwa 1976; Vismer et al. 1980; Kamalam and Thambiah 1982; Drouhet and Ravisse 1993; Nazir et al. 1997). In a few patients, oral ketoconazole (Piens et al. 1985), itraconazole (Gugnani 1999), and fluconazole (Davis et al. 1994; Gugnani et al. 1995) have sometimes been successful, but amphotericin B has seldom been helpful (Khan et al. 2001). Some more recent reports have demonstrated the successful use of combination potassium iodide and ketoconazole (Bittencourt et al. 1991) and itraconazole and fluconazole (Valle et al. 2001). Surgical resection alone is not curative (Kwon-Chung and Bennett 1992). In one series of gastrointestinal infection, all patients were successfully treated by the combination of surgical resection of the infected portions of the gastrointestinal tracts and itraconazole therapy, and this may be the treatment of choice for these patients (Lyon et al. 2001). In vitro antifungal susceptibility testing of nine isolates of *B. ranarum* reported low minimum inhibitory concentrations (MIC) to the azoles fluconazole, itraconazole, ketoconazole, and miconazole (Guarro et al. 1999).

In patients with submucosal infections caused by *Conidiobolus* spp., treatment options have so far been disappointing. Surgical resection of infected tissue is seldom successful and may even hasten spread of infection. Potassium iodide solution, amphotericin B, and trimethoprim–sulfamethoxazole have all been used with mixed success (Martinson 1971; Herstoff et al. 1978; Kwon-Chung and Bennett 1992). Some more recent reports of successful treatment include using fluconazole (Gugnani et al. 1995), or combination therapy with amphotericin B and terbinafine (Foss et al. 1996) and ketoconazole plus potassium iodide (Mukhopadhyay et al. 1995). In vitro resistance to amphotericin B, 5-fluorocytosine, fluconazole, itraconazole, ketoconazole, and miconazole has been reported for seven isolates of *Conidiobolus* (Guarro et al. 1999). In the rare cases of disseminated infections caused by *C. incongruus*, only one of three patients has survived following surgical debridement and amphotericin B treatment (Busapakum et al. 1983; Walsh et al. 1994; Dromer and McGinnis 2003). There is a single patient report of an 18-month-old girl with periorbital cellulites secondary to *C. incongruus* who initially failed amphotericin B therapy was successfully treated by radical resection with antifungal chemotherapy and hyperbaric oxygen (Temple et al. 2001).

Chromoblastomycosis is a non-contagious, chronic, localized fungal infection of cutaneous and subcutaneous tissues caused by several species of pheoid (dematiaceous) fungi. The disease is characterized by the presence in infected tissues of brown, thick-walled, multiseptate, fungal forms known as muriform bodies (synonym: sclerotic cells, Medlar bodies) (Figure 1). The etiologic agents of chromoblastomycosis are black molds that are found world-wide growing as saprophytes of wood, other vegetation and soil (Gezuele et al. 1972; Dixon et al. 1980; Iwatsu et al. 1981; Okeke and Gugnani 1986) (Table 1). Infection follows traumatic implantation of the etiologic agent beneath the epidermis via penetration by foreign bodies such as wood splinters and tree thorns, or other minor wounds or abrasion. After implantation, the pseudo-yeast cells undergo a morphological change into the distinctive muriform bodies, and the fungus persists in this form within the infected host tissue. Nearly all cases of chromoblastomycosis are accounted for by the species *Fonsecaea pedrosoi*, *Cladophialophora carrionii* (*Cladosporium carrionii*) and *Phialophora verrucosa*. The disease is reported most frequently in individuals living in tropical and subtropical regions, notably the West Indies, Brazil, Northern Venezuela, and Madagascar, but it is cosmopolitan in distribution. The actual prevalence and incidence of chromoblastomycosis are unknown because of sporadic reporting, but in areas where interest and endemicity are high, rates of infection have ranged from 1 per 32 500 population to one per 7 000 population (Ajello 1970). In some villages in Madagascar and Northern Venezuela, the prevalence is as high as 1 per 480 inhabitants (Esterre et al. 1996) or even higher (Rodrigues et al. 1992). Historically, chromoblastomycosis has usually been refractory to treatment, but two recently developed antifungal compounds, itraconazole and terbinafine, appear to hold promise for a greatly improved prognosis in many cases.

HISTORY

The earliest known discovery of the fungal etiology of chromoblastomycosis was made by Alexandrino Pedroso in 1911 in São Paulo, Brazil, when he observed muriform bodies in nodular and ulcerated foot and leg lesions of a patient, and recovered the pheoid mold known today as *Fonsecaea pedrosoi.* Pedroso did not publish his observations, however, until 1920 (Carrion and Silva 1947). In the meantime, Max Rudolph had published, in 1914, his clinical observations from cases encountered in the Brazilian states of Minas Gerais and Goiás. In 1915, Medlar and Lane of Boston became the first investigators to publish clinical observations that were supported by positive culture results. The etiology in their case was *Phialophora verrucosa*.

Subsequently, the nomenclature for infections caused by these fungi became confused. Following the initial clinical reports, chromoblastomycosis was known by several names (McGinnis 1983). The name chromoblastomycosis (*chromo* = coloured; *blasto* = budding)

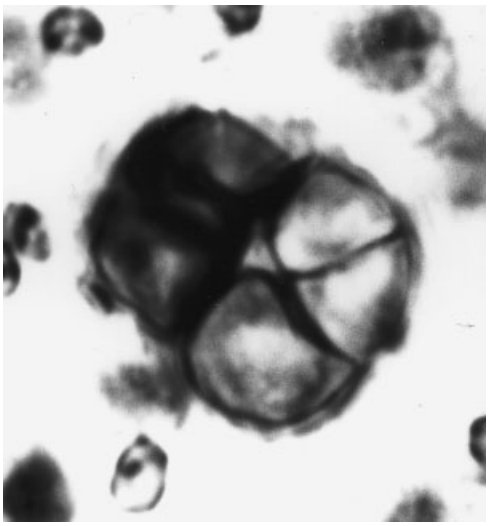

Figure 1 *Muriform bodies, pathognomonic for chromoblastomycosis, are subglobose, 5–13 μm in diameter, multiseptate, and dark brown in color as a result of the synthesis of melanin within the cell walls.*

was first proposed in 1922 (Terra et al. 1922). A later proposal, however, reasoned that the term 'chromoblastomycosis' is a misnomer because muriform bodies multiply by splitting apart rather than by budding, and therefore a more appropriate name would be chromomycosis. Further confusion arose from the occasionally indiscriminate use of both these terms to refer to an assortment of infections caused by pheoid fungi, irrespective of whether or not the characteristic muriform bodies were formed in tissue.

To eliminate ambiguity caused by misapplication of these two terms, the name chromoblastomycosis was retained in its original sense, chromomycosis was rejected, and the name pheohyphomycosis was coined to encompass infections caused by pheoid fungi that are clinically and pathologically different from chromoblastomycosis (Ajello et al. 1974; McGinnis 1983). Pheohyphomycosis is characterized by pheoid fungi that grow in infected tissue as pseudohyphae, hyphae, or any combination of these forms, but not as muriform bodies. It is caused by at least 100 fungal species, and has clinical features that generally differ from chromoblastomycosis. Today, the distinctions embodied by the terms 'chromoblastomycosis' and 'pheohyphomycosis' have become widely accepted. As for most biological phenomena, however, efforts to categorize the manifestations of pathogenic fungi have seldom been entirely satisfactory. For example, the two leading agents of chromoblastomycosis, *P. verrucosa* and *F. pedrosoi*, have been encountered in rare cases that can best be characterized as mycetoma and pulmonary pheohyphomycosis, respectively (Morris et al. 1995; Turiansky et al. 1995). Although there is some overlap, there is diagnostic utility in maintaining the two clinical terms, stemming from the strong predictive correlation of morphology in tissue with etiology, clinical course, and prognosis.

ECOLOGY AND EPIDEMIOLOGY

Virtually all cases of chromoblastomycosis are caused by the species *F. pedrosoi*, *C. carrionii*, and *P. verrucosa*. Additional fungi, including *Fonsecaea compacta* (McGinnis and Schell 1980), *Rhinocladiella aquaspersa* (Borelli 1972; Schell et al. 1983), *Exophiala spinifera* (Barba-Gomez et al. 1992; Padhye et al. 1996), *Cladophialophora arxii* (Tintelnot et al. 1995), *Phaeosclera dematioides* (McGinnis et al. 1985), *Botryomyces caespitosus* (de Hoog and Rubio 1982), *Sporothrix schenckii* var. *luriei* (Padhye et al. 1992) and *Wangiella (Exophiala) dermatitidis* are also capable of forming muriform bodies in infected tissue but, with the exception of *W. dermatitidis*, these species are exceedingly rare as etiologic agents of infection in humans. Infections resulting from *W. dermatitidis* occur occasionally and are typified in tissue by short chains of spherical cells that have 0–1 septa; only very rarely do muriform bodies form, and for this reason most mycologists consider the species to be an agent not of chromoblastomycosis but of pheohyphomycosis.

Worldwide, *F. pedrosoi* causes the great majority of infections. *C. carrionii*, in addition to *F. pedrosoi*, is particularly common in Australia, Southern Madagascar and South Africa. *P. verrucosa* is reported in smaller numbers from various temperate to subtropical climates. The reasons for regional variation in the relative etiologies seemed to be linked to local ecological conditions. For example, investigation of natural and clinical isolates in Australia between 1957 and 1961 has suggested that *C. carrionii* is particularly likely to occur in drier regions that have as little as 500 mm of annual rainfall (Ridley 1961). In 1960, Brygoo and Segretain reached a similar conclusion for Madagascar, finding that *C. carrionii* was predominant in a spiny desert region of 500–600 mm of annual rainfall, whereas *F. pedrosoi* infections predominated in regions having annual rainfall of 2200–3200 mm. These observations were later extended by a retrospective study of 170 clinical isolates in Madagascar from 1970 to 1994 (Esterre et al. 1996). This study found that in the southern dry region, all cases of chromoblastomycosis (representing more than 38 percent of the total cases in Madagascar) were caused by *C. carrionii*, whereas in the evergreen forest region of much greater rainfall only *F. pedrosoi* (62 percent of the total sample) was encountered. Sources of saprobic strains of *C. carrionii* provide additional support for the concept that this species can exist in dry substrata, such as soil in Arizona (USA) (Padhye 1986), fence posts in Australia and Nigeria made from *Eucalyptus cebra* (Ridley 1961) and a *Pinus* sp. (Okeke and Gugnani 1986) and cactacae in northern Venezuela (Richard-Yegres and Yegres 1987). Morphological

identification of muriform-like cells was even made in the medulla of two cactus species (Zeppenfeldt et al. 1994) (see Table 1). *P. verrucosa* seems to be the third most common etiologic agent, after *F. pedrosoi* and *C. carrionii*, and has been reported from North, Central, and South America, Asia, and Africa. In one study, it was concluded that isolates of *P. verrucosa* were more likely to be encountered in relatively cooler climates than warmer climates; five of six isolates of *P. verrucosa* among 90 cases of chromoblastomycosis came from temperate regions as opposed to subtropical and tropical regions (Carrion and Silva 1947). It is of interest that the relative proportions of species among clinical isolates do not necessarily agree with relative proportions among environmental isolates. For example, Fukushiro (1983) found 86 and 1.6 percent of chromoblastomycosis in Japan to be caused by *F. pedrosoi* and *P. verrucosa*, respectively, whereas Iwatsu et al. (1981) were able to culture only one isolate of *F. pedrosoi*, in contrast to 17 isolates of *P. verrucosa* from environmental sources in Japan.

Cutaneous and subcutaneous infections begin when the fungus is introduced by a break in the dermal barrier. In rare instances, splinters that presumably harbored the fungus and initiated the infection were found within infected tissue (Mead and Ridley 1957; Tschen et al. 1984; Connor and Gibson 1985). In one case of chromoblastomycosis that developed following

abrasion by the branch of a tree, investigators were able to return to the site 2 months later and isolate the etiologic agent by culturing portions of the branch (Rubin et al. 1991). Although some patients are able to recount specific trauma to the affected site as a possible initiating event, some as recently as 3 weeks before (Gruber et al. 1988), most patients cannot specifically recall any precipitating injury. Presumably, this is because the initiating event was often trivial or unnoticed, and symptoms, which may not occur until much later, can be mild and seemingly of little consequence initially. It is also typical that there is a considerable delay in the medical diagnosis of chromoblastomycosis. For example, in Madagascar, where there is both a relatively high prevalence of infection and a high awareness on the part of local healthcare providers, the average time of diagnosis is 1–4 years after initial symptoms arise (Esterre et al. 1996). Probable factors for delay in medical diagnosis include the gradual and indolent nature of the infection and, in some localities, a limited availability of easily accessible healthcare.

Chromoblastomycosis has been reported in most regions of the world, but is more common in tropical and subtropical settings, as evidenced by Carrion who found that 79 percent of reviewed cases occurred in patients living in such climates (Carrion and Silva 1947). Furthermore, most of these individuals resided in rural areas and were involved in agricultural or related activities. In one rural tropical region of Brazil where mycoses are a relatively frequent finding, chromoblastomycosis has remained one of the most common of the serious mycoses (Talhari et al. 1988). Most patients were between 30 and 55 years of age, and there seems to be no predilection for any particular race, because the regions of high endemicity have included populations of European, African, or Asian origin (Carrion and Silva 1947; Al-Doory 1972; Lavalle 1980; Tsuneto et al. 1989). The role of gender is unclear; mostlarge reports have concluded that infections are more likely to occur in men than in women, but othershave found female patients in equal or greater numbers (Carrion and Silva 1947; Campins and Scharyj 1953; Al-Doory 1972; Bansal and Prabhakar 1989; Tsuneto et al. 1989; Hiruma et al. 1993; Esterre et al. 1996). It is probable that these contradictory findings merely reflect the difference in sex ratios within various occupations in different cultures and geographical regions.

Chromoblastomycosis occurs most often in individuals who have no apparent underlying illness or debility. However, some preliminary data suggest that a genetic susceptibility to chromoblastomycosis might exist. In a study of 32 infected people and 77 control individuals, the presence of HLA antigen A29 was linked to a 10-fold increase in susceptibility to chromoblastomycosis (Tsuneto et al. 1989). Other people who are at risk of developing infections are those whose immune system is impaired as a result of organ transplantation or corticosteroid use (Nishimoto et al. 1984; Morales et al. 1985; Wackym et al. 1985; Perry and Sheretz 1987; Greene et al. 1990). In countries where these medical modalities are widely used, such patient populations may constitute potential for an increasing prevalence of chromoblastomycosis. Infections have also been noted in conjunction with malignancy (Foster and Harris 1987; Hiruma et al. 1992) and leprosy (Pavithran 1988; Lacaz et al. 1994), although the significance of these observations is unknown. Chromoblastomycosis has been rarely reported in animals including dogs, horses (Abid et al. 1987), toads (Bube et al. 1992) and frogs, although only some of the reports are well documented. The infection is not known to be transmissible from animals or between humans.

MYCOLOGY

In terms of mycological classification, the phylogeny of the suspected fungi has not been conclusively established and the species are currently placed into form-taxa within a parallel system of classification known as the Deuteromycota. It is suspected that the fungi, which cause chromoblastomycosis, may be related to the family *Herpotrichiellaceae*, order Ophiostomatales, phylum Ascomycota (de Hoog et al. 1995), but no sexual stage has yet been discovered in the lifecycle of any of the causative species. As this classification necessarily employs highly artificial and potentially unreliable criteria, attempts at classifying species usually do not extend above the genus level. However, those species classified in the Deuteromycota and which contain large amounts of melanin in their cell walls, causing the colony color of these species to range from pale gray or brown to black, are often collectively referred to as the black or pheoid fungi. Based on this common feature, they are sometimes ascribed the status of a form-family, the *Dematiaceae* (Matsumoto et al. 1994; Pappagianis and Ajello 1994).

Individual species of these pheoid opportunistic pathogens are identified primarily based upon various features of their microscopic morphology, including characteristics of the conidia (spores) and the cells from which the conidia arise. Some of these species are pleomorphic, meaning that they have the ability to form more than one asexual reproductive morphology in culture. Each of these different morphs is sometimes given a separate latinized name for technical reasons, as permitted by the International Code of Botanical Nomenclature. Thus, the identification process for pleomorphic isolates can be problematic. In such instances, the accepted approach has been to choose the most distinctive, conspicuous and stable morph as the basis of the binomial name (identification) that will be applied to the isolate. Any accompanying morph that is present may be referred to using a separate genus level name.

However, the Code permits taxonomists to disagree about which morph should be chosen as the basis of the binomial. For example, in the case of *F. pedrosoi*, the *Fonsecaea* morph usually predominates, and a *Rhinocladiella* morph is often well represented, whereas a very few examples of a *Phialophora* morph can sometimes be seen as well. For this reason, some taxonomists have chosen to name the fungus *F. pedrosoi* whereas others prefer *Rhinocladiella pedrosoi*. The reader is referred for further discussion of this matter to the literature (McGinnis and Salkin 1993; Schell et al. 1995).

Newer methods of identification are less practical for clinical work, but are considered to be more reflective of phylogeny, and thus have had impact upon the taxonomy of these organisms (Honbo et al. 1984a; de Hoog et al. 1995). For example, results from restriction fragment length polymorphism (RFLP) patterns of mitochondrial DNA (Kawasaki et al. 1999) or large subunit RNA analysis (de Hoog et al. 1995) have led to the confirmation of *F. pedrosoi* as an homogeneous species or the reclassification of *Cladosporium carrionii* as *Cladophialophora carrionii*.

IDENTIFICATION

Fonsecaea pedrosoi

Colonies are olivaceous–black, slow in growth rate, and velvety in texture. Conidiogenous cells are cylindrical, usually with an irregularly swollen apex that is studded with scars from conidial attachment. Conidia measure approximately (1.5–2.5) × (3.5–5) μm, are one celled and broadly clavate with a flat base. Each conidium usually gives rise to several additional conidia in a repeating process that ultimately forms a complexly branched head consisting of three to four levels of conidia (Figure 2). A *Rhinocladiella* morph (Figure 3) is usually present, and a *Phialophora* morph (Figure 4) can also be present (McGinnis and Schell 1980). *F. pedrosoi* can easily be confused with *Cladosporium* spp. and *Rhinocladiella* spp. (Schell et al. 1995).

Cladophialophora carrionii (*Cladosporium carrionii*)

Colonies are olivaceous–black, slow in growth rate, and velvety in texture. Conidiophores bear outwardly spreading, sparsely branching, long chains of ellipsoidal, symmetrical, one-celled conidia that measure approximately (2.2–2.6) × (4.5–6.0) μm (Figure 5). A *Phialophora* morph can also be present (Trejos 1954; Honbo et al. 1984a, b). This species can easily be confused with *Cladosporium arxii*, *Cladosporium* spp., *F. pedrosoi*, and *Cladophialophora bantiana* (Schell et al. 1995).

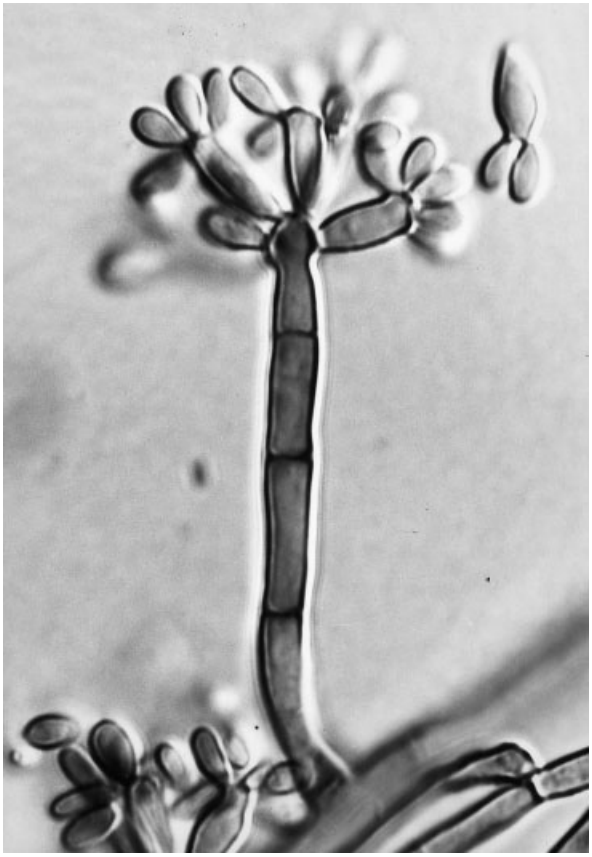

Figure 2 Fonsecaea pedrosoi *can produce conidia by multiple mechanisms. Usually, conidia arise from the swollen apex of the conidiophore, and then give rise to additional conidia, resulting in two to four levels of conidia formation. This form is termed the 'Fonsecaea synanamorph,' and is generally considered to be the most distinctive.*

Phialophora verrucosa

Colonies are olivaceous–black, slow in rate of growth, and velvety in texture. Conidiogenous cells are phialides, vase-like in shape, with a prominent collarette (Figure 6). Conidia measure approximately (1.5–2.5) × (2.5–4.5) μm, are one-celled, ellipsoidal, and emerge sequentially from phialides to accumulate in subglobose masses. The species can be confused with other species of *Phialophora* and *Fonsecaea* (Schell et al. 1995).

CLINICAL PRESENTATIONS OF CHROMOBLASTOMYCOSIS

In its various stages, chromoblastomycosis can mimic the following:

- a foreign body granuloma (Wackym et al. 1985)
- a ganglion cyst (Jayalakshmi et al. 1990)
- lupus (Molina Lequizamon et al. 1984)
- leprosy (Banks et al. 1985; Pavithran 1992)
- leishmaniasis or cutaneous tuberculosis (Boudghene-Stambouli and Merad-Boudia 1994)

Figure 3 Fonsecaea pedrosoi *also often sporulates by forming each conidium sequentially at the continually elongating tip of the conidiophore. This form is termed the '*Rhinocladiella *synanamorph' based upon its resemblance to fungi in the genus* Rhinocladiella.

Figure 4 Fonsecaea pedrosoi *can sometimes sporulate by forming phialides, where conidia emerge from a cup-like orifice in a sequential process. This is termed the '*Phialophora *synanamorph' because of its resemblance to the fungus* Phialophora verrucosa. *In this figure, a portion of the* Fonsecaea *synanamorph is also visible.*

- keratoacanthoma (Wiss et al. 1986)
- cutaneous sarcoidosis (Perry and Sheretz 1987)
- common wart (Jayalakshmi et al. 1990)
- malignancy (Pavlidakey et al. 1986; Jayalakshmi et al. 1990; Hiruma et al. 1992).

Lesions of chromoblastomycosis most often arise on an extremity and usually begin as small scaly papules or nodules which are painless but may be itchy (Fukushiro 1983). Satellite lesions may gradually arise from auto-inoculation as a result of scratching the lesions, or by spread of the fungus through the lymphatic system (Carrion and Silva 1947; Takase et al. 1988; Hiruma et al. 1992). Rash-like areas enlarge and become raised irregular plaques, often scaly or verrucose (Figure 7). Lesions in cases of long duration can become large, tumorous and even cauliflower-like in appearance (Figure 8). Flat lesions that exhibit central healing and scarring can sometimes be seen. Blood, serous, or caseous material can often be expressed from lesions (Carrion and Silva 1947). Damaged tissue, clotted blood, and fungal cells are expelled through the epidermis by the process of transepithelial elimination and are deposited in the form of small dark aggregations at the surface of the lesion (Uribe et al. 1989). These are commonly known as black dots, and can be selectively removed and examined microscopically for the diagnostic presence of muriform bodies.

Other prominent features of chromoblastomycosis are epithelial hyperplasia, microabscess formation in the epidermis, and dermal fibrosis. There are data to suggest that intense extracellular matrix cross-linking, associated with the sustained contribution of transforming growth factor beta (TGF-β)-activated fibroblasts, exists in tissues of chromoblastomycosis compared with healthy tissue and tissue from other chronic skin infections. Keloid-like irreversible fibrosis seems to result from lysyl oxidase-mediated pyridinoline (Esterre et al. 1992) and transglutaminase-mediated glutamyl-lysine (Esterre et al. 1998b) collagen cross-linking.

Chromoblastomycosis is slowly progressive and can persist for decades if neglected or not successfully treated. An analysis of cases for a 20-year period in Jamaica found a mean duration of 8 years, and a range of 3 months to 27 years (Bansal and Prabhakar 1989). A persistence up to 30 years has been recorded in the Malagassy focus (Esterre et al. 1996). Untreated lesions can progress to involve an entire limb, although muscle and bone do not become infected. In the absence of adequate management, chromoblastomycosis is a

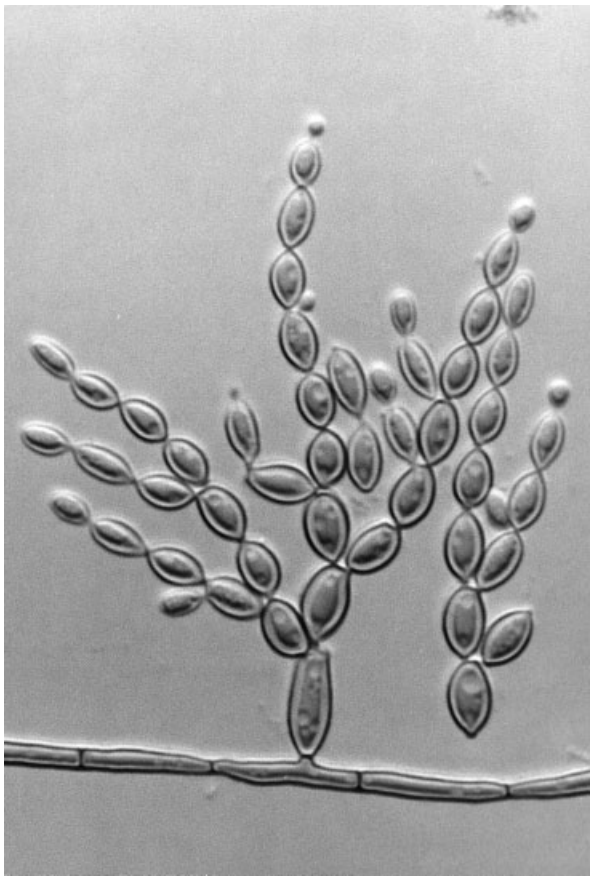

Figure 5 Cladophialophora carrionii *forms conidia in acropetal, occasionally branched, chains.*

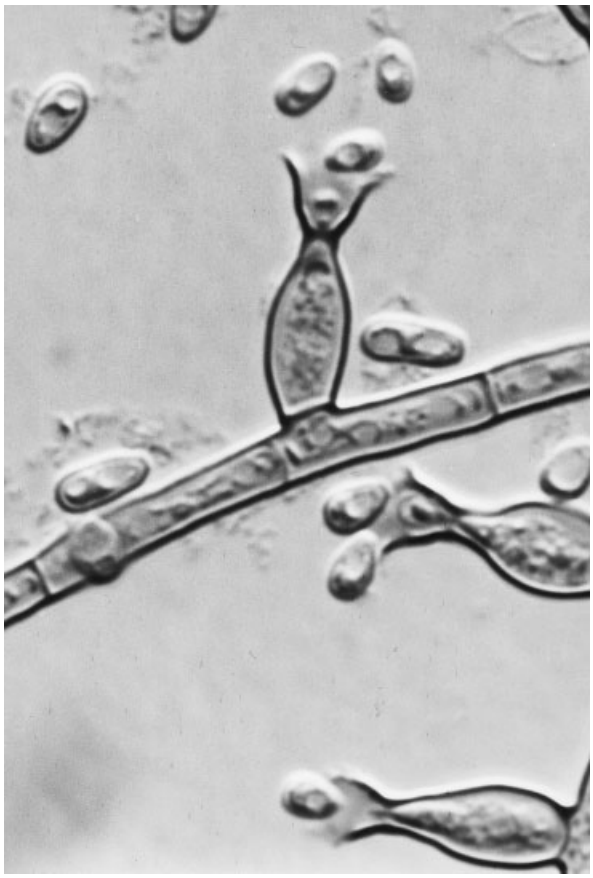

Figure 6 Phialophora verrucosa *sequentially forms conidia at the orifice of phialides which bear distinctive cup-like collarettes.*

chronic, progressive, and recalcitrant disease that may eventually become incapacitating. Complications include secondary bacterial infections, lymphostasis, swelling and contraction of the affected limb. For those living in tropical climates, feet and legs are the parts of the body that are most frequently subjected to minor wounds involving soil and vegetation; as a result, the disease most often involves these sites, although any exposed part of the body is vulnerable (Nakamura et al. 1972; Iwatsu et al. 1983; Zaror et al. 1987; Gruber et al. 1988; Gross and Schosser 1991; Hiruma et al. 1992; Esterre et al. 1996 and Figure 9). Hematogenous spread and cerebral infections are rare complications, and seem to occur only with *F. pedrosoi* in Japan (Fukushiro 1983). Primary infection of the lung has only been reported twice for *F. pedrosoi* (Zaharopoulos et al. 1988; Morris et al. 1995).

HISTOPATHOLOGY

Muriform bodies are the characteristic tissue form of all agents of chromoblastomycosis. They are pheoid, thick-walled, multiseptate bodies, 5–13 μm in diameter and are typically found at the surface of the lesions (see Figure 1). The host tissue response is a granulomatous reaction with polymorphonuclear neutrophils, sometimes showing ultrastructurally a frustrated phagocytosis pattern (Esterre et al. 1993), and macrophages infiltrate and formation of numerous microabscesses. Muriform bodies are found singly or in clusters within the microabscesses, and sometimes within giant cells

Figure 7 *Chromoblastomycosis lesions are often scaly or crusty, and frequently feature small, dark aggregations of clotted blood and fungal cells (right). A portion of the lesion (left) had been biopsied the preceding day.*

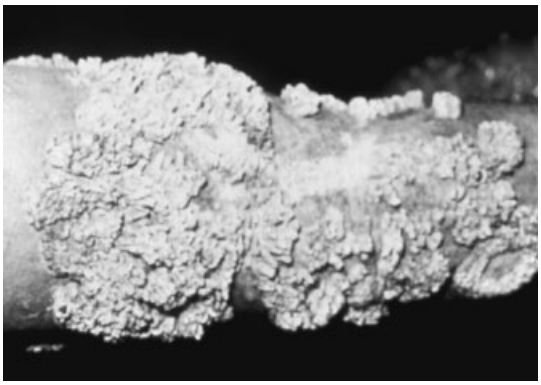

Figure 8 *Chromoblastomycosis of many years' duration can result in large, verrucous or cauliflower-like lesions. (Courtesy T.G. Mitchell.)*

(Fukushiro 1983; Uribe et al. 1989). Epitheliomatous hyperplasia is generally present. Melanin is produced in the cell walls of the muriform bodies, which results in a dark-brown coloration that can easily be seen in histological sections stained with hematoxylin and eosin. They routinely divide, not by budding as seen in yeasts, but by separation along the interface of double septa. Budding of the muriform bodies is sometimes seen, but is not believed to contribute significantly to multiplication. Muriform bodies can be induced in vitro under defined conditions, and experimental data suggest that the concentration of calcium ions within infected tissue may play a role in regulating in vivo dimorphism (Mendoza et al. 1993). Detecting the presence of muriform bodies establishes a diagnosis, but as all etiologic agents of chromoblastomycosis have the same features in tissue, the particular species involved in a case can be determined only by recovery of the fungus in culture.

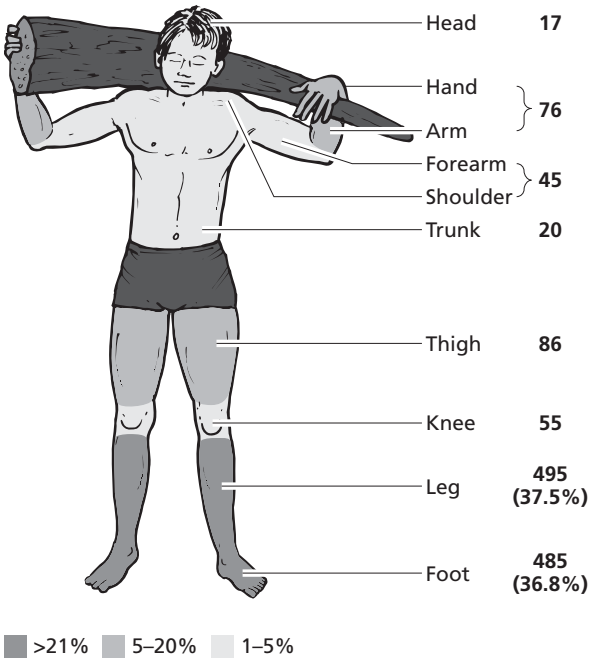

Figure 9 *Distribution of skin lesions observed on 1 316 cases, during a 40-year (1955–94) epidemiologic survey in Madagascar.*

IMMUNOLOGY AND SEROLOGY

Relatively little is known about the immunological aspects of chromoblastomycosis, but evidence so far demonstrates that host responses to fungal antigens occur at both cellular and humoral levels. Antibodies against the causative fungi have been detected by various methodologies in a high percentage of patients (Villalba 1988; Villalba and Yegres 1988; Esterre et al. 1997a, 2000), including some asymptomatic cases in endemic areas (Esterre et al. 1997a). Experimentation using animals has suggested that purified rabbit IgG can substantially inhibit growth of *F. pedrosoi* in culture (Ibrahim-Granet et al. 1988), but whether these findings reflect a role for protective immunity in humans against this mycosis is not yet certain. Host cellular response has been experimentally demonstrated in mice. Fungal cell wall lipids coated on to charcoal particles induced significant granulomatous reactions in mice for agents of chromoblastomycosis, as compared with control charcoal particles (Lacaz and Ekizlerian 1985).

In addition, a preparation of fractionated non-lipid cell wall material common to four etiologic agents has been found to induce a granulomatous reaction and death in mice, thereby showing that nonlipid cell wall components, as well as lipids, are capable of causing a cell-mediated host reaction (Lacaz and Fazioli 1985). Data from a recent clinical study of eight patients with chromoblastomycosis, compared with healthy control patients, suggest that individuals with chromoblastomycosis exhibit a normal cellular response to bacterial antigens, but that a partial suppression of cell-mediated immune response to fungal antigens arises at some point during the infection. The authors have suggested that such suppression may play a role in the pathogenicity of these fungi (Fuchs and Pecher 1992). Skin-test antigens have been prepared in research settings, and limited testing has found reactivity among patients diagnosed with chromoblastomycosis. Skin testing of larger population subsets to determine the extent of exposure to the etiologic fungi has not been attempted, but an enzyme-linked immunosorbent assay (ELISA)-based survey has been organized in the endemic eastern region of Madagascar, revealing a 6 percent level of seropositivity in the whole population (Esterre et al. 1997a).

LABORATORY DIAGNOSIS

As chromoblastomycosis can be confused with many other afflictions, it is necessary to establish the diagnosis through laboratory testing before proceeding with specific treatment. Serological testing for chromo-

blastomycosis is reportedly very sensitive (Esterre et al. 2000), but is not widely used because the necessary specialized reagents are not available commercially. By contrast, microscopy and culture provide highly sensitive means of diagnosis that are both simple and inexpensive. The most rapid diagnostic technique is collection of skin scrapings or a biopsy specimen from the active margin of the lesion and examination microscopically in 10–20 percent KOH for the presence of muriform bodies. So-called black dots, which are often present on the lesion's surface, are most likely to contain the muriform bodies and are excellent specimens (Zaias and Rebell 1973). In unusual cases, superficial crusts from lesions or specimens from pulmonary infection may show septate, pheoid hyphae instead of muriform bodies (Carrion and Silva 1947; Lavalle 1980; Fukushiro 1983; Morris et al. 1995). The addition of the fluorescent reagent calcofluor white to the KOH procedure has greatly increased the sensitivity of microscopic examination for most mycotic infections. However, it is not reliable for detecting heavily melanized fungal cells, such as muriform bodies, and therefore should not be the only method of microscopic examination used in suspected cases of chromoblastomycosis.

When microscopy is negative, culture can establish the diagnosis because of its superior sensitivity as a clinical procedure. As all agents of chromoblastomycosis have the same morphology in tissue, culturing the fungus is the only means of establishing the etiology in a given case, and is a prerequisite if antifungal susceptibility testing is to be performed. Furthermore, because of the current proliferation of newly developed antifungal compounds, it is important to culture and correctly identify causative fungi before instituting therapy so that potential patterns of clinical resistance or susceptibility to individual drugs can eventually become recognized and utilized by the medical community.

TREATMENT

Historically, successful treatment of chromoblastomycosis has been exceedingly difficult. Surgical excision of small areas of infection has provided the most reliable means of cure. Successful surgery necessarily requires removal of a margin of uninfected tissue. In addition to traditional surgical management, success has been reported with cryosurgery using liquid nitrogen in 11 patients infected with *F. pedrosoi* (Pimentel et al. 1989), with CO_2 laser surgery in one case (Kuttner and Siegle 1986) and with Mohs' micrographic surgery in another (Pavlidakey et al. 1986). Both thiabendazole and flucytosine (5-fluorocytosine), an orally administered drug, have led to improvement in several cases where excision was not feasible. As a result of toxicity from metabolites of flucytosine, however, it is necessary to monitor the level of this drug in the patient's serum during the course of therapy.

The first consistently effective antifungal compound for infections caused by pheoid fungi appears to be the new triazole itraconazole. No prospective, controlled trials have yet been conducted for this compound but evidence so far indicates that cures and significant improvements can be expected for many patients, even for some who have failed to respond to other therapies. In one series of 19 patients with inoperable lesions caused by *F. pedrosoi*, duration of their infections ranged from 6 to 36 years, with 14 patients having had previous therapy. All the patients responded to itraconazole therapy, with eight patients achieving clinical and biological cure (Queiroz-Telles et al. 1992). From Natal, South Africa, a report suggests that itraconazole is especially effective for infections with *C. carrionii* (Bayles 1992).

Another new oral compound, terbinafine, has been recently investigated for infections caused by pheoid fungi. An open pilot study in two hospitals in Madagascar, using 500 mg/day during 6–12 months, reported a high clinical and mycological efficiency (about 85 percent) without significant adverse reactions nor relapse during a 2-year follow-up (Esterre et al. 1997b, 1998a). Short treatments (3–4 months) or 250 mg/day dose have been tested with success on recent lesions (Esterre et al. 1997b) and even poorly responsive patients could be cured by a combination therapy with oral itraconazole (200–400 mg/day) and terbinafine (250–750 mg/day) (Gupta et al. 2002). In addition to its fungicidal properties, terbinafine revealed two unexpected and interesting bypass effects at the skin level: an antifibrotic activity (Esterre et al. 1998a; Esterre and Ricard-Blum 2002) and a reversal of immunological anergy (Elewski et al. 2002).

Unfortunately, both itraconazole and terbinafine are expensive at present and therefore of limited affordability. An inexpensive approach that has yielded good results in several cases is treatment with topical heat. Chemical and electric pocket warmers and heat bulbs resulted in cures for 15 of 19 *F. pedrosoi* infections in one reported series (Hiruma et al. 1993). Spontaneous resolution of untreated lesions has been reported but appears to be a rare occurrence (Nishimoto et al. 1984).

INTRODUCTION

Sporotrichosis is a varied disease caused by a single dimorphic fungal species, *Sporothrix schenckii*. It occurs worldwide, growing as a mold in association with dead or senescent plant material. When cells of the mold gain entry to a susceptible animal host, they transform into budding yeast cells and persist as such within the infected tissue. Sporotrichosis most commonly presents as a chronic ulcerative infection of cutaneous and subcutaneous tissue, and tends to spread along channels of the lymphatic system. These cutaneous and lymphocutaneous infections typically are initiated by trauma or minor abrasion from plant material harboring cells of the fungus. Lesions normally develop within 3–12 weeks following inoculation. In unusual instances, the fungus can spread from lesions in subcutaneous tissue to nearby joints, or more rarely to other organs. Pulmonary sporotrichosis is an infrequent syndrome which starts when airborne conidia from the mold, growing as a saprobe upon natural substrata, are inhaled into the alveoli of the lungs. In such cases, an infection can develop that resembles other chronic lung infections such as tuberculosis and histoplasmosis.

Sporotrichosis is a cosmopolitan disease and is probably the most frequently encountered subcutaneous mycosis in the world. Most cases occur among people living in tropical and subtropical regions, and the disease is relatively common in Mexico, Uruguay, and Brazil. In Brazil, the national incidence of sporotrichosis is second only to paracoccidioidomycosis among the deep mycoses (Costa et al. 1994). In Sao Paulo, sporotrichosis has accounted for as much as 0.5 percent of all mycoses for which medical attention was sought (Sampaio et al. 1954). The number of cases in North America has been estimated at 2.4 per million population per year, but because the mycoses have never been designated as notifiable (reportable) diseases, the true incidence of sporotrichosis remains unknown (Ajello 1970; Reingold et al. 1986).

HISTORY

The first case report and documentation of the fungal etiology of sporotrichosis appeared in 1898 in the USA (Schenck 1898). By 1932 about 200 infections had been reported in the USA (Jacobson 1932), and there was subsequently a rapid increase in reported cases in this and other countries (Mackinnon 1948; Goncalves and Peryassu 1954; Sampaio et al. 1954; Mayorga et al. 1978; Lavalle and Mariat 1983; Reingold et al. 1986; Rippon 1988; Talhari et al. 1988). In Japan, for example, 13 cases had been reported as of 1945, but since that time more than 2 500 cases have been dealt with by the Japanese healthcare system (Fukushiro 1984). A retrospective study at one dermatology clinic in Japan found that 0.17 percent (150 patients) of all patients entering the clinic were diagnosed with sporotrichosis (Kusuhara et al. 1988), and similar findings were reported from a second clinic (ltoh et al. 1986; Eisfelder et al. 1993). By

contrast. there has been some recent evidence to suggest an overall decline in the prevalence of sporotrichosis in parts of Japan from 1983 onwards, as well as a decrease in the number of infections in Europe, possibly resulting partly from a decreasing number of people being engaged in agriculture (Alberici et al. 1989; Barile et al. 1993; Eisfelder et al. 1993). Epidemiologic data from about 822 cases were recorded in a 37-year period in Jalisco, Mexico (Mayorga et al. 1997) and a review, mainly about epidemiology, microbiology, and treatment, was published in 2001 (De Araujo et al. 2001).

Sporotrichosis continues to be a chronic problem for public health programs in certain rural areas of the world; in addition, there are newer aspects of the disease that are particularly relevant in urban and suburban settings. One of these is the emergence of sporotrichosis within the subpopulation of people who are seropositive for the human immunodeficiency virus (HIV). A second recently recognized aspect is the potential for zoonotic infections, particularly those contracted from the domestic cat *Felis catus*. Several medical therapies are available for the treatment of sporotrichosis, and cure of the lymphocutaneous form of infection can be achieved with relative ease. By contrast, pulmonary, skeletal, and disseminated infections can be very difficult to manage and are life-threatening conditions.

ECOLOGY AND EPIDEMIOLOGY

Sporothrix schenckii is widespread in nature and can be isolated as a saprobe from dead or senescent vegetation, such as thorns, hay, straw, sphagnum moss, and wood. For this reason, sporotrichosis is a recognized occupational hazard for nursery and forestry workers, and is also often associated with farmers, florists, leisure gardeners, and others whose occupation or avocation brings them into frequent and sometimes traumatic contact with plant material or soil. The great majority of infections arise under such circumstances, as reflected by one of the common names for sporotrichosis – 'rose gardener's disease.' Also at risk are people who work as manual laborers in rural areas and who wear little protective clothing or footwear, and thus have increased potential for exposure to the fungus (Forester 1924; Lavalle and Mariat 1983; Itoh et al. 1986).

Children comprise a significant portion of sporotrichosis patients, and presumably acquire most of these infections while playing or helping with chores out of doors (Rudolph 1984; Prose et al. 1986; Frumkin and Tisserand 1989; Yamada et al. 1990). Two reports from Mexico have shown that as many as 10–25 percent of sporotrichosis patients in that country are children (Leon 1964; Solano 1966). Retrospective examination of records at a university in Japan has shown that children under the age of 12 have a particularly high rate of infection. The face is a frequent site of infection in children, as evidenced by a finding that 92 percent of 529 pediatric cases of sporotrichosis included lesions of the face (Fukushiro 1984; Eisfelder et al. 1993).

A report of 238 cases occurring in a relatively remote area of the south central highlands of Peru showed 60 percent in children and the most commonly affected anatomic site was the face. The incidence of sporotrichosis in this region ranged from 48 to 60 cases per 100 000 persons and was highest among children aged 7–14 years, approaching one case per 1 000 persons (Pappas et al. 2000). In Mexico, 10–34 percent of cases are children, the youngest patient has been a child, 2 days old, who acquired sporotrichosis after a rat bite and the oldest a 117-year-old man. Lymphocutaneous forms are observed in 65–82 percent, fixed forms in 20–30 percent and the systemic ones in 2–5 percent (Mayorga et al. 1997; Arenas 2003).

Cluster infections can occur when people are exposed to a common source of inocula. Past examples of small outbreaks included 12 workers in two geographical regions who were infected by hay mulch (Cook et al. 1984), six students who became infected by packing straw (Sanders 1971), four workers who were infected by sphagnum moss at a garden center (Remington et al. 1982), four people who contracted infections from a contaminated camping tent (Campos et al. 1994), and two employees of a meat packing plant who developed pulmonary infection, presumably from a common source (Dewan et al. 1986).

A 32-year-old white man developed lymphocutaneous sporotrichosis at the same site as a self-administered tattoo on the dorsal aspect of the left foot, but he stated that he had mowed the lawn wearing only sandals on the same day that he had tattooed his foot (Bary et al. 1999). Cutaneous sporotrichosis evolved in a 20-year-old woman who underwent electrolysis on the anterior aspect of her neck (Ditmars and Maguina 1998) and a case of *Sporothrix* conjunctivitis was described as an atraumatic infection (Hampton et al. 2002).

ln addition, there are numerous reports of multiple people contracting sporotrichosis from an infected cat (Table 1).

More rarely, sporotrichosis can occur in epidemic proportions. The largest reported outbreak of sporotrichosis occurred during 1941–44 when at least 2 899 cases were seen among gold miners in the Transvaal region of South Africa (du Toit 1942; Helm and Berman 1947). Of these, 2 441 occurred in several levels of a single mine, although a total of at least nine mines was involved in the outbreak. The fungus was found to be growing upon timbers used to shore the mine shafts, and infections would begin when bare skin was abraded by the colonized timbers. The epidemic was brought under control by application of a fungicidal compound to the timbers (Brown and Weintroub 1947), and formaldehyde fumigation of clothing and living quarters (du Toit 1942). All infections were cured using oral potassium

Table 1 *Zoonotic sporotrichosis transmitted by* Felis catus

Vector	No. of infected humans	Associated trauma	Reference
1 cat	3	3	Larsson et al. 1989

a) 89 of 42 people denied incurring trauma from the cats.

iodide daily for 4–5 weeks in most cases (Helm and Berman 1947; Quintal 2000).

The largest single outbreak in the USA occurred in 1988, infecting 84 people in 15 states and spanning a distance of hundreds of kilometers. These individuals, most of whom were forestry workers, became infected from handling sphagnum moss that had been applied to the roots of tree seedlings in order to humidify and protect them during shipment from central nurseries (Coles et al. 1992). Sphagnum is also used by nurseries to protect seedling roots from cold storage conditions during the winter season. Contaminated sphagnum moss, used in horticulture or forestry activities, has caused additional outbreaks (Gastineau et al. 1941; Crevasse and Ellner 1960; Hayes 1960; D'Alessio et al. 1965; Storrs et al. 1969; Powell et al. 1978; Grotte and Younger 1981; Remington et al. 1982; Cote et al. 1988). Nearly all of the sphagnum harvested in the USA grows in bogs in central Wisconsin.

Although sporotrichosis has long been linked in North America to the handling of sphagnum moss, it is still unknown at what point the fungus comes into association with the moss. Environmental sampling from earlier moss-related outbreaks suggested that *S. schenckii* is likely to be found in conjunction with harvested moss that has become wet during storage, rather than with moss that has been continually stored under dry conditions (McDonough et al. 1970; Powell et al. 1978). During investigation of the 1988 outbreak, samples of moss taken at the point of harvest were found to be culture negative for *S. schenckii*. Pond water used at one of the nurseries to dampen the moss before its use as packing material was also culture negative. Additional testing under laboratory conditions showed that *S. schenckii* did not grow on living sphagnum, but would grow very quickly on dead sphagnum in the presence of adequate humidity and warmth. Thus, it is suspected that *S. schenckii* can be introduced into sphagnum during or after harvest, but that the moss does not pose an infectious hazard as such, until it becomes moistened and warmed to an extent that allows the fungus to multiply (Zhang and Andrews 1993). Similar findings have been reported with regard to hay (Cook et al. 1984).

An outbreak was associated with stored hay or hay bales harvested in a military installation in southwestern Oklahoma. Four patients had maintained hay bales in a house and the fifth patient had visited the house once. As in three previous reports, this contact with hay should be recognized as a risk factor for infection with *S. schenckii* (Dooley et al. 1997).

Although most infections originate when the fungus is introduced by splinters, thorns, abrasions, and other minor wounds, there is evidence to suggest that a wound of the cutaneous barrier is not essential for infection to occur. Experimental results obtained with human subjects in conjunction with the African epidemic showed that one in 10 developed sporotrichosis when a thick suspension of viable conidia was placed onto the skin, covered with gauze, and allowed to incubate (Simson et al. 1947). A 1924 report attributed the source of an infection to the handling of contaminated bandages from lesions of a patient who was being treated for sporotrichosis (Forester 1924). In 1992, there was a compelling incident further suggesting that a wound is not a prerequisite for initiation of cutaneous

sporotrichosis. In this instance, infection developed on the finger of a researcher who had used a mortar and pestle to homogenize a strain of *S. schenckii* (Cooper et al. 1992). Molecular typing of both the isolate cultured from the lesion and the stock culture that the researcher had worked with showed that they were the same strain of *S. schenckii*. Molecular typing has been used in additional cases to establish the source of infection (Reed et al. 1993), and to suggest that a person can be simultaneously infected with more than one strain of *S. schenckii* (Kobayashi et al. 1990).

As these accounts imply that sporotrichosis can sometimes develop without a preceding breach of the dermal barrier, the question of contagion warrants consideration. Historically, sporotrichosis has not been considered a transmissible infection even though rare instances of person-to-person spread had been suggested long ago (Forester 1924; Smith 1945). Recent reports, such as that of an infection apparently passed from the arm of a woman to the face of her 3-year-old child, give cause to reconsider this potential aspect of sporotrichosis (Jin et al. 1990). It was a series of animal-acquired infections, however, that provided some of the strongest evidence that, in some circumstances, infections can be contagious and possibly occur through the invasion of apparently intact dermis. The infections in these cases were acquired from domestic cats. In one example, all four family members developed sporotrichosis from their infected pet. When the cat was presented for veterinary care, a veterinary technician and a veterinary student also contracted sporotrichosis soon after handling the animal. Significantly, none of the infected individuals could recall being scratched or bitten by the cat (Read and Sperling 1982).

In another example, a veterinary technician wore gloves and had no wounds while examining an infected cat but 3 weeks later developed lesions of sporotrichosis at the cuff line where glove protection ended (Dunstan et al. 1986b). Infections attributed to cats are known from at least four continents. A recurring feature of interest in these reports is that many patients were certain that they had not been wounded during handling of the infected animals. At a minimum, 43 infections in humans have been attributed to 26 cats, and 26 of 42 people for whom information was available denied incurring trauma from the animal (see Table 1).

It has long been known that cats are quite susceptible to sporotrichosis (Barbee et al. 1977). It is not clear how cats become infected, but in one instance eight people contracted infections from two cats that frequented a site where sphagnum moss had been used in landscaping. One possibility is that the fungus might adhere to the feet and claws of the cats, and lesions could arise as the inocula are implanted during fights between animals (Dunstan et al. 1986b). Another possibility is the inclination of cats to rub repeatedly against rough or thorny vegetation, which could initiate lesions of sporotrichosis. A related observation is that lesions in cats can be teeming with cells of the fungus (Werner et al. 1971; Nusbaum et al. 1983; Dunstan et al. 1986b; Marques et al. 1993; Reed et al. 1993). This is in stark contrast to lesions in humans where cells of *S. schenckii* are typically very sparse. It has been suggested that a potentially heavy load of organisms in the lesions of cats may be related to the high number of transmissions to humans and to the lack of evident trauma in some of these cases. In view of these reports, it should become accepted medical practice that patients with sporotrichosis be questioned to ascertain whether pets, particularly cats, may have been the source of infection, and that such animals be investigated as a potential threat to the health of other people.

In southeastern Brazil, four cases of human sporotrichosis transmitted by domestic cats were described. There was a previous history of a cat scratch before the development of the lymphocutaneous lesions. In cats, the lesions were multiple, extensive, necrotic, exudative, and ulcerated. In two necropsied cats, disseminated lymphatic and visceral mycotic infection was observed and histopathology revealed widespread histiocytic reaction with a large number of fungal organisms (Fleury et al. 2001).

In Rio de Janeiro over a period of 12 years (1987–98), 13 cases of human sporotrichosis were recorded. Two of them were associated with the scratch of a sick cat. During the subsequent two years (1998–2000), 66 human, 117 cats and seven dogs with sporotrichosis were diagnosed. Fifty-two human (78.8 percent) reported contact with cats with sporotrichosis, and 31 (47 percent) reported a history of a scratch or bite. This epidemic involving cats, dogs, and human beings is unprecedented in the literature, and may have started insidiously before 1998 (Kauffman 1999; Bastos de Lima-Barros et al. 2001; Schubach et al. 2001). In the study in Brazil, 72 of the cats (61.5 percent) were male with ages between 3 months and 18 years (median 2 years). The majority of the cutaneous lesions were located on head (46.6 percent) and limbs (35.9 percent). Most of the cases were from the underprivileged areas of the city. Nowadays, veterinarians, technicians, and cat owners or caregivers should be considered to be new categories at risk of acquiring the mycosis. The zoonotic potential of feline sporotrichosis is possibly due to the large number of organisms detected in feline tissues (Bastos de Lima-Barros et al. 2001).

Sporotrichosis has also been attributed to wounds inflicted by various other animals. Two well-documented cases occurred in young boys, each of whom was bitten by a captured field mouse (Moore and Davis 1918; Frean et al. 1991). In another rodent-related report, a rancher developed sporotrichosis after killing and handling gophers that had numerous cutaneous lesions (Olson 1912). Sporotrichosis has also been documented in a number of other animals including the armadillo,

boar, camel, cattle, chimpanzee, dog, dolphin, donkey, fowl, fox, horse, mule, and rat (Kaplan et al. 1982).

The relationship of sporotrichosis to the armadillo is remarkable. It has been established that *S. schenckii* can be found on vegetation lining the burrows of armadillos (Mackinnon et al. 1969). In Uruguay, two armadillo species, *Dasypus novemcinctus* and *Dasypus septemcinctus*, are hunted as game. For a 16-year period, of 138 cases for which the source of infection could be discerned, 81 percent were attributed to contact with armadillos, their burrows or equipment used in hunting them (Conti-Diaz 1980). Of the remaining infections, wounds from plants or other objects caused 15 percent and 4 percent, respectively. Furthermore, it was shown that infections were most numerous during the peak hunting months, and that very few cases of sporotrichosis were seen during the armadillo breeding season when hunting is traditionally suspended. The indigenous population has long been aware of this association and refers to sporotrichosis as *mulita* (armadillo) sickness (Conti-Diaz 1980). Sporotrichosis has also been found in two wild armadillos (*D. novemcinctus*) captured in the USA for purposes of leprosy research (Kaplan et al. 1982). The widespread exposure of various animals to *S. schenckii* has been demonstrated experimentally by skin-testing surveys. In Sao Paulo, testing of 96 zoo animals with sporotrichin, a skin-test antigen derived from *S. schenckii*, showed a positivity rate of 57 percent among terrestrial animals and 4 percent among arboreal animals (Costa et al. 1994).

Sporotrichosis has also been reported in the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), and there has been suggestion that it could possibly be associated with fish as well (Migaki et al. 1978). In Guatemala, 53 cases of sporotrichosis were observed during a 3-year period among people living in the Lake Ayarza District (Mayorga et al. 1978). Of 30 patients able to recall injury, six infections were attributed to trauma by woody material, but 24 individuals recounted trauma associated with handling fish taken from the lake. A report from South America relates an infection attributed by the patient to a knife wound sustained while cleaning fish (Beer-Romero et al. 1989).

Based on these types of reports, it seems that the role of animal vectors should probably be given greater attention in the consideration of the epidemiology of sporotrichosis. Outbreaks of the kind associated with sphagnum moss are dramatic, but may prove to be the easiest to prevent or control (Coles et al. 1992). By contrast, the potential for zoonotic infections remains high, and in some settings does not readily lend itself to prevention strategies.

S. schenckii has been also been encountered as a saprobe from a variety of unexpected substrates. It has been recovered from commercial potting soil (Kenyon et al. 1984), found as a food contaminant of meat sausages (Ahearn and Kaplan 1969) and culinary mushrooms (Kazanas and Jackson 1983), and found growing in a container of intravenous fluid at a medical center (Matlow et al. 1985). *S. schenckii* has been recovered from samples taken for routine microbiological monitoring of various surfaces within an indoor swimming pool complex. Although the fungus was detected in moderate numbers from swabs of wall and floor surfaces, no plants or wooden materials, which could have provided a substrate for amplification of the organism, were found in the building (Staib and Grosse 1983). No infections were associated in any of these instances.

The pandemic spread of HIV has brought particular attention to the mycoses, in that most of the acquired immune deficiency syndrome (AIDS)-defining illnesses are fungal infections. Sporotrichosis is now one of the opportunistic infections encountered in very small numbers among AIDS patients (Lipstein-Kresch et al. 1985; Shaw et al. 1989; Heller and Fuhrer 1991; Perfect et al. 1993; Bolao et al. 1994; Donabedian et al. 1994). Only about a dozen cases have been reported to date, but sporotrichosis in HIV-seropositive patients is extremely serious. In patients whose conditions have deteriorated to clinical AIDS, sporotrichosis becomes disseminated and the prognosis is grave. Disseminated infection can involve one or more joints or organ systems, including the central nervous system (CNS). Such infections are problematic not only from the standpoint of therapy but also from the basis of diagnosis. As the AIDS epidemic spreads, there are certain to be more cases of disseminated sporotrichosis. Whether the prevalence of sporotrichosis in this group of people can be expected to increase is unknown.

There appears to be no relationship of gender to sporotrichosis. Although some reports have suggested that patients are more likely to be men, others have shown nearly equal ratios and a few have noted a preponderance of female patients (Conti-Diaz 1980, 1989; Fukushiro 1984; Itoh et al. 1986; Kusuhara et al. 1988). Differences among these reports may result from varying sex distributions for occupations and tasks among the differing regions, and thus might correlate with frequency of exposure to the fungus rather than a gender-based predilection for infection. Statistics from the recent USA outbreak suggest that gender was not a risk factor, and that the greatest predictor of infection in this particular series was the duration of exposure to the fungal-ridden moss (Coles et al. 1992).

In a recent report in Mexico, the frequency was higher in women (62 percent), children, and adolescents under 20 years of age (34 percent) and adults older than 50 years of age (28 percent) (Espinosa-Texis et al. 2001).

MYCOLOGY

It has long been recognized that the genus *Sporothrix* has accommodated a heterogeneous assemblage of

morphologically similar species. One species, *Sporothrix cyanescens*, has been found to possess a septal ultrastructure that clearly shows affinity to the basidiomycetes. and so has been transferred to the genus *Cerinosterus* as *Cerinosterus cyanescens* (Smith and Batenburg-van der Vegte 1985). A teleomorph of *S. schenckii* has not been conclusively demonstrated in spite of many attempts at mating various clinical and environmental isolates. Nevertheless, as a result of similarities in morphology of the conidial morph formed by the ascomycete *Ophiostoma (Ceratocystis) stenocera* as compared with conidial formation in clinical isolates of *S. schenckii,* a phylogenetic relationship was surmised (Mariat 1971; de Hoog 1974). By contrast, studies of the polysaccharides and DNA base composition in these two taxa did not support this conclusion (Travassos and Lloyd 1980). Similarly, subsequent mitochondrial DNA typing by restriction fragment length polymorphism (RFLP) analysis showed a great deal of variation among isolates of *S. schenckii*, and this led to the conclusion that *S. schenckii* and *O. stenocera* may not be of the same holomorph (Suzuki et al. 1988). However, recent comparison of 18S rRNA gene sequence characters found that *S. schenckii* (two strains) and *O. stenocera* (one strain) differed at only three sites of the 1 700 nucleotides sequenced (Berbee and Taylor 1992). These findings strongly support the conclusion that *S. schenckii* is, or was at one time, the anamorph of an *Ophiostoma* spp. As a result of the wide variation in morphological and molecular characteristics reported thus far in these fungi, testing of additional strains is warranted. Presently, *S. schenckii* is classified in the mitosporic fungi (deuteromycetes).

S. schenckii synthesizes melanin via the 1,8-dihydoxynaphthalene pentaketide pathway, and this dark pigment has been found exclusively in the conidia, which are the infecting structures of this organism. Cultures of a reddish-brown mutant were identified by thin-layer chromatography, high-performance liquid chromatography, and ultraviolet (UV) spectra and material believed to be melanin was absent in conidial walls of the albino mutant. These results demonstrate that melanin may protect *S. schenckii* against certain oxidative antimicrobial compounds and against attack by macrophages, because melanized cells are less susceptible to oxidative killing in vitro and to phagocytosis by human monocytes and murine macrophages (Romero-Martinez et al. 2000).

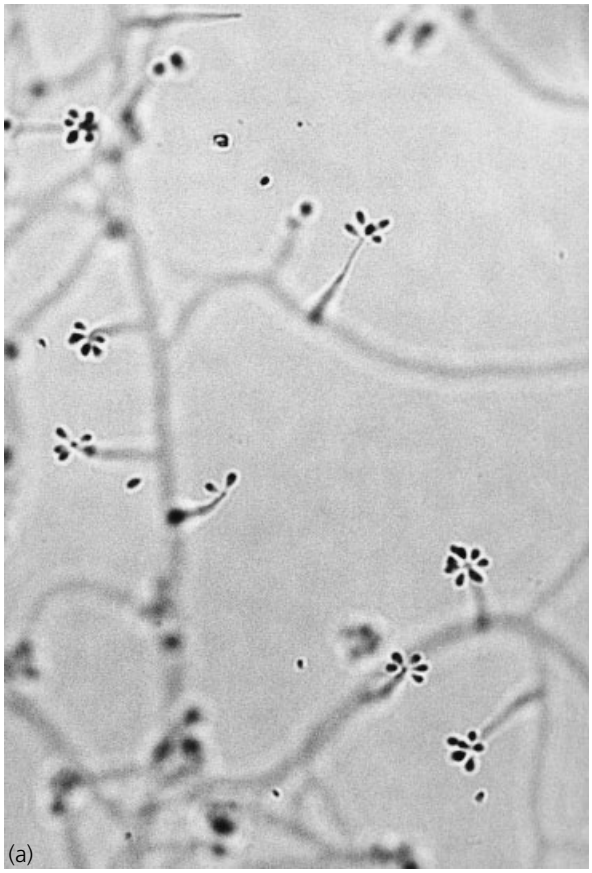
IDENTIFICATION

Growth of *S. schenckii* can usually be observed within 3–5 days on culture media incubated at 30°C. Colonies typically are cream-colored initially, smooth and moist, gradually becoming dark brown and filamentous in texture. There is, however, much variation among isolates and even among subcultures of the same isolate. Some remain smooth and exhibit few or no aerial hyphae; others remain white to cream-colored with little or no brown pigmentation, or are brown during all stages of growth. Texture and coloration are also influenced by various culture media. Microscopic features include elongated conidiophores with a swollen, scarred apex which bears one-celled, obovoid (egg-shaped), hyaline to subhyaline conidia that measure approximately (1.4–2.5) × (2–4) μm; these are sometimes in radial 'flower-like' clusters (Figure 1). Isolates also form thick-walled conidia borne laterally along the hyphae, with each conidium being individually attached to the hypha (Figure 2).

These conidia are usually subglobose but can be triangular in some isolates. They can be colorless, but usually are dark brown and are chiefly responsible for the dark color of the colony. The various species in the genus *Sporothrix* are similar in appearance, but only *S. schenckii* is known to be pathogenic for humans and other animals. In addition, several other genera bear morphological resemblance to the genus *Sporothrix* (de Hoog 1974; de Hoog et al. 1985). For these reasons, in the absence of positive histology, it is necessary to confirm the identity of a suspected isolate of *S. schenckii*. This is accomplished by proving that, in addition to having both conidial forms as described above, the isolate will grow in a stable yeast-Iike form at 35–37°C (Figure 3). It should be noted that environmental, nonpathogenic isolates of *Sporothrix* spp. can grow as a yeast at 35–37°C, but lack the thick-walled, pheoid conidia that are attached individually along the hyphae (Dixon et al. 1991). When cultured at 35–37°C on chocolate agar or other enriched media, most isolates of *S. schenckii* will quickly show partial or complete conversion to a stable yeast-Iike form. Occasional isolates are more difficult to convert and may require extended incubation (up to 3 weeks) or frequent subculturing of the isolate (Kwon-Chung 1979). Some isolates from fixed cutaneous lesions reportedly will grow at 35°C but not at 37°C, and this thermal limitation was also shown through experimentation with mice (Kwon-Chung 1979). Other investigators have been unable to demonstrate this difference in isolates from fixed cutaneous lesions (de Albornoz et al. 1995).

A murine model suggest that the virulence of *S. schenckii* conidia may be determined by their cell wall composition. The more virulent forms of the fungus showed differences in cell wall sugar composition with rhamnose:mannose molar ratios of 1.7:1.0 for cells cultured for 4 days and 1.0:1.7 for conidia cultured for 12 days (Fernandes et al. 1999).

The interaction between *S. schenckii* and several extracellular matrix (ECM) proteins have been studied since adhesion is the first step involved with the dissemination of pathogens in the host. *S. schenckii* can bind to fibronectin, laminin, and type II collagen and also show



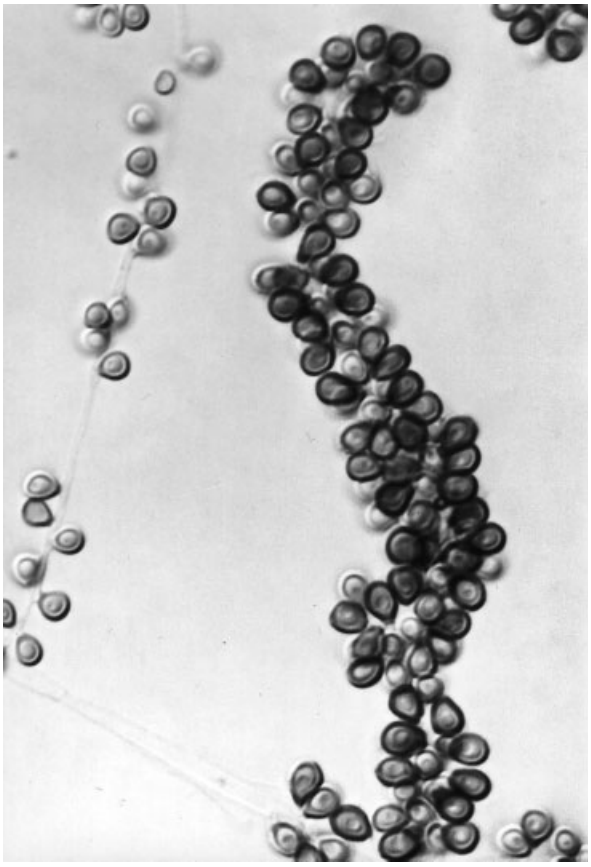


Figure 2 S. schenckii *also forms conidia that are thick-walled, dark brown as a result of melanin formation and attached directly to the hyphae, often in a dense sleeve-like manner.*

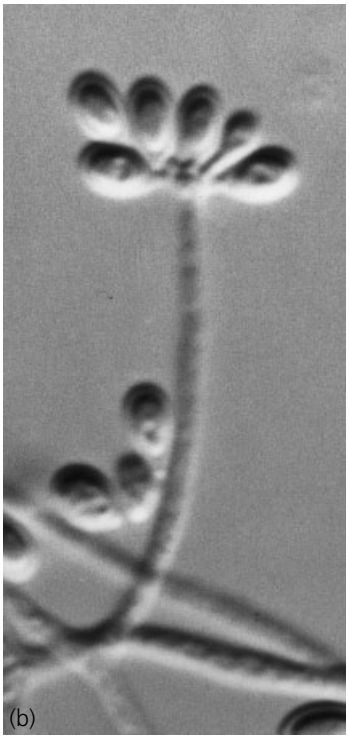

Figure 1 S. schenckii *forms conidia in a radial manner, each being attached to the apex of the conidiophore, resulting in a flower-like appearance.*

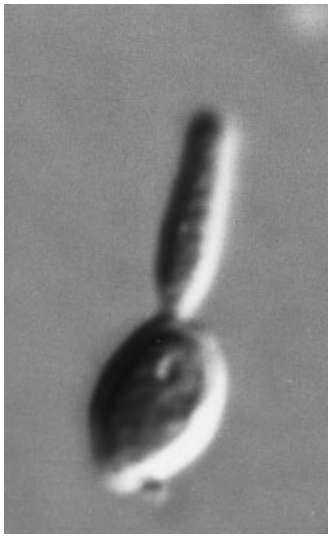

Figure 3 *In vitro conversion of* S. schenckii *from the mold to the yeast phase can be induced using a rich medium incubated at 35–37°C. Buds will often exhibit a characteristic cylindrical or 'cigar' shape.*

differences in binding capacity according to the morphological form of the fungus (Lima et al. 1999).

A new variety, *S. schenckii* var. *luriei*, was described in 1969 based on a case of sporotrichosis in which the fungal morphology manifested in host tissue was significantly different from that of typical sporotrichosis. Three cases have now been reported. In these infections, the fungus exhibited large (10–30 μm), subglobose to elongated, thick-walled (up to 2 μm) cells (Ajello and Kaplan 1969; Alberici et al. 1989; Padhye et al. 1992). These cells each formed a single septum that allowed separation into two separate cells. During separation, a fragment of the cell wall previously shared by the two cells can temporarily remain attached in a bridge-Iike manner, giving the fungus the distinctive appearance of spectacles. In some instances, a second septum would form, giving the fungus a muriform appearance. In the absence of culture, it is possible that the histological appearance of this new variety could be mistaken for chromoblastomycosis, although its cells do not contain visible amounts of melanin as seen in chromoblastomycosis. Mitochondrial DNA typing has also confirmed that *S. schenckii* var. *luriei* is markedly different from *S. schenckii* var. *schenckii* (Suzuki et al. 1988). In culture, whether as a mold or a yeast, *S. schenckii* var. *luriei* is morphologically indistinguishable from *S. schenckii* var. *schenckii.* There is insufficient experience with this variety to know if there are associated serological, therapeutic, or prognostic differences.

UV exposure of *Sporothrix* strains produces a high frequency of morphological variants and one common feature among them was that they were smaller in size compared to the wild type. These findings suggest that there is a highly sensitive chromatin in the conidial genome that is the target of UV light (Torres-Guerrero and Arenas-López 1998).

CLINICAL PRESENTATIONS OF SPOROTRICHOSIS

Sporotrichosis can be mistaken for numerous skin diseases including pyoderma gangrenosum (Spiers et al. 1986; Liao et al. 1991), rosaceae (Day et al. 1984), sarcoma (Sen et al. 1986) and leishmaniasis (Talhari et al. 1988). A recent field study in Brazil found that most patients with an initial diagnosis of leishmaniasis were infected instead with *S. schenckii* (Dr Aloisio Falqueto, personal communication).

Three cases of coinfection of leishmaniasis with *Sporothrix* spp. in the same lesion have been described in rural areas where people frequently try to remove the scabs using thorns or wooden splinters, thereby facilitating the entry of *S. schenckii*, which is present in the same geographic areas as *Leishmania* spp. (Agudelo et al. 1999)

Confusion with other diseases can lead not only to delay of suitable therapy, but also to the use of anti-inflammatory corticosteroids which can cause marked proliferation of the fungus within the lesions and a worsening of the infection (Bickley et al. 1985; Padhye et al. 1992). In a recent outbreak involving 84 patients, only 11 were correctly diagnosed at their first medical evaluation; 48 cases were misdiagnosed as bacterial infections, six as spider bites and two as cancer (Coles et al. 1992). In another series, the average delay in correct diagnosis was 4 months overall and 25 months for cases of extracutaneous sporotrichosis (Rowe et al. 1989).

The typical clinical presentation of sporotrichosis is that of a chronic cutaneous and subcutaneous infection. In these cases, lesions begin as a firm nodule, which initially is fluctuant but which gradually becomes immovable. The nodule becomes softened and in most cases eventually ulcerates to discharge pus or serous material (Figure 4). Satellite lesions will sometimes arise. A review of 235 cases showed that 23 percent were characterized by such fixed cutaneous lesions (Sampaio et al. 1954). Furthermore, facial lesions in children are often of this type (Fukushiro 1984; Eisfelder et al. 1993). In most cases, however, yeast cells from the initial lesion are phagocytosed and carried into the lymphatic system where a line of cutaneous ulcerative lesions then develops in an ascending fashion along lymph channels (Figure 5). *S. schenckii* has been isolated from blood, but such a finding is rare (Morgan et al. 1984; Kosinski et al. 1992).

In Mexico, upper limbs are affected in 45–53 percent, the face in 14–21 percent, lower limbs in 18–23 percent, and it is exceptional in the trunk (Arenas 2003). Lymphangitic forms account for 82 percent (Espinosa-Texis et al. 2001).

Complications in sporotrichosis are unusual, but the disease can be very refractory to medical management. Skeletal involvement (Atdjian et al. 1980; Arenas and Latapi 1984; Chang et al. 1984; Kumar et al. 1984; Yacobucci and Santilli 1986; Yao et al. 1986; Janes and Mann 1987; Wilson et al. 1988; Govender et al. 1989) is encountered often enough for sporotrichosis to be considered in the differential diagnosis of patients presenting with chronic joint disease. Reviews have

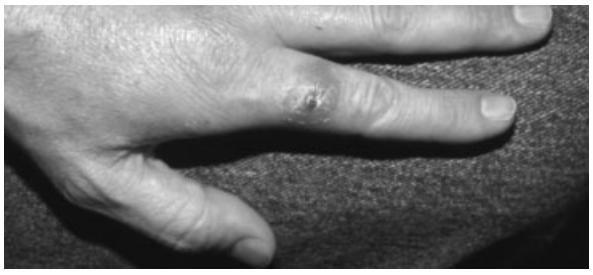

Figure 4 *Solitary cutaneous sporotrichosis lesion on the finger of a professional rose gardener*

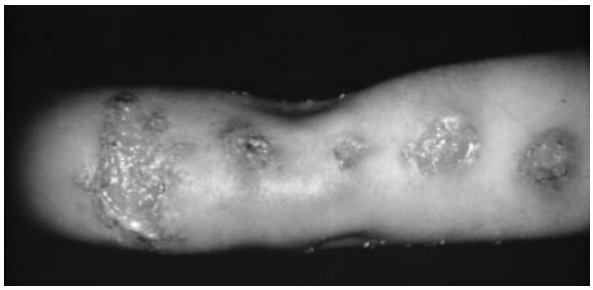

Figure 5 *Lymphangitic sporotrichosis ulcers develop in an ascending fashion along channels of the lymph system. (Courtesy T.G. Mitchell)*

noted that 1–14 percent of cases of sporotrichosis involve one or more joints (Rowe et al. 1989; Ortiz and Lefkovitz 1991). Joint infection also has been noted in the absence of accompanying skin lesions (Ortiz and Lefkovitz 1991).

Sporothrix arthritis is a rare disease and should be considered to be a monoarthritis, with only 51 cases reported in the English literature. Most of the patients have been middle-aged men who have a significant alcohol intake (77 percent). Seventeen joints have been affected and in 20 percent the knees were involved (Howell and Toohey 1998)

Dissemination, which can involve the CNS, has historically been relatively rare (Smith et al. 1981; Selman and Hampel 1982; Friedman and Doyle 1983; Morgan et al. 1984; Aronson 1992). However, cases of sporotrichosis now being seen in AIDS patients are usually disseminated, fatal infections (Lipstein-Kresch et al. 1985; Kurosawa et al. 1988; Shaw et al. 1989; Heller and Fuhrer 1991; Bolao et al. 1994; Donabedian et al. 1994). Extracutaneous sporotrichosis can also occur in organ transplant recipients who are receiving immunosuppressive therapy for the prevention of organ rejection (Gullberg et al. 1987; Agarwal et al. 1994).

Sixty-three widely distributed cutaneous lesions were observed in a female host with both humoral and cellular immunity within normal limits, but who was under treatment with long-term prednisone (Severo et al. 1999).

Although the typical clinical presentation of sporotrichosis is that of a chronic cutaneous and subcutaneous infection, *S. schenckii* has also caused eye infections (Schell 1986; Rippon 1988), sinusitis, infection of the vocal cords (Smith et al. 1981; Agger and Seager 1985), pyelonephritis (Agarwal et al. 1994) and pulmonary infections. Pulmonary sporotrichosis has been increasingly documented (Rohatgi 1980; Friedman and Doyle 1983; Nusbaum et al. 1983; Pluss and Opal 1986; Pueringer et al. 1986; Heller and Fuhrer 1991) and is suspected of being more common than is generally realized (Lavalle and Mariat 1983; England and Hochholzer 1985, 1987; Gerding 1986; Pluss and Opal 1986; Pueringer et al. 1986; Watts and Chandler 1987; Rippon 1988; Haponik et al. 1989; Farley et al. 1991).

A recent 30-year review at one institution found that 4 percent of sporotrichosis cases were pulmonary infections (Rowe et al. 1989). This form of the disease follows inhalation of conidia that have become airborne from the mold as it grows upon organic substrata in nature. The infection is insidious and sometimes asymptomatic. Symptoms include low-grade fever, weight loss, night sweats, productive cough with or without hemoptysis, and pleuritic pain. Radiological examination of the lungs can reveal adenopathy, nodules or cavitation, usually involving the upper lobes, or diffuse involvement similar to that seen with tuberculosis (Comstock and Woolson 1975; Rohatgi 1980; Pluss and Opal 1986). Ethanol abuse is found in conjunction with some cases of sporotrichosis, especially pulmonary and joint ínfections, but the reasons for this apparent association are not known.

HISTOPATHOLOGY

Histological examination of lesions reveals a central necrotic region with associated infiltration of neutrophils, macrophages, and giant cells. Yeast cells are usually not seen using routine histological methodology, but can be detected through examination of serially sectioned tissue that has been stained with special fungal stains. This approach reveals areas of host tissue reaction to the fungus and indicates where the yeast cells are likely to be found. The yeast cells of *S. schenckii* are often solitary and quite round in shape, 3–5 μm in diameter, mostly without apparent budding (Figure 6). Asteroid bodies (Figure 7) and cylindrical 'cigar-shaped' buds are often cited as characteristic microscopic features in cases of sporotrichosis, but both these can be difficult to demonstrate in many cases. Asteroid bodies are stellate-shaped conglomerations which develop from host–parasite interactions and can be seen in other diseases in addition to sporotrichosis.

Electron micrography of asteroid bodies obtained from cases of sporotrichosis suggests that materials from disintegrated host cells, particularly polymorphonuclear neutrophils, are deposited upon the surface of the fungal

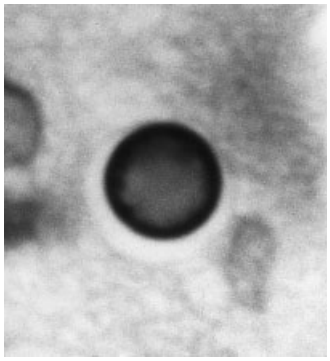

Figure 6 S. schenckii *cells in infected tissue are rare in number, round to ellipsoidal, 3–5 μm, yeast-like, with or without obvious budding.*

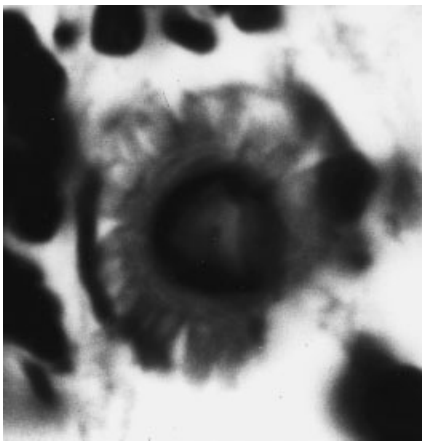

Figure 7 *Asteroid bodies consist of degenerate materials from the host immune response that accumulate in a ray-like manner upon the yeast cells of* S. schenckii, *giving them a stellate appearance.*

cell and are subsequently crystallized through an unknown process. The result is a multilayered accretion which features an outer layer of low electron density that appears to contain fragments of cell membrane-Iike material (Hiruma et al. 1991, 1992a). In lesions where the fungus is abundant, cells of *S. schenckii* can be within the macrophages, and sometimes exhibit a staining artifact of a halo or capsule. In these instances, sporotrichosis can be mistaken for *Histoplasma capsulatum* var. *capsulatum* (Nusbaum et al. 1983; Farley et al. 1991; Aronson 1992).

The characteristic infiltrates in three zones (central suppurative, tuberculoid, and peripheral round cell) were found in 27.27 percent, the asteroid bodies in 18 percent, and the yeast cells in 32 percent. The histopathological findings usually offer clues to the diagnosis and in just a few cases when the yeast cells are found, it can be diagnostic (Ruiz-Esmenjaud et al. 1996).

Asteroid bodies and yeast cells with budding, highly suggestive of the disease, were seen in the cytological and histological preparations obtained with fine-needle aspiration (FNA) cytology (Zaharopoulos 1999).

IMMUNOLOGY AND SEROLOGY

Data suggest that exposure to *S. schenckii* is widespread in many populations, and that the host immune response is able to resolve most inoculum challenges. Antigens prepared from *S. schenckii* have permitted small-scale studies of skin-test reactivity to be conducted in areas of both high and low endemicity (Ajello 1970). Results from studies of a prison population and a hospital population in the USA showed delayed hypersensitivity reactions occurring in 11 percent and 10 percent of individuals, respectively. In comparison, people involved in high-risk occupations were found to have a much greater prevalence of skin-test positivity. Of workers tested in a plant nursery, 33 percent were reactive; for those workers employed for at least 10 years, the rate of positive skin tests was 58 percent. In Brazil, skin testing in a small group from the general population yielded a reactivity rate of 24 percent. These findings suggest that exposure to *S. schenckii* is more common than the number of clinical infections indicates, and that most infections are asymptomatic and self-limiting. Occasional clinical observations of apparent spontaneous remission support this notion for both cutaneous and pulmonary infections (Powell et al. 1978; Bargman 1981; Iwatsu et al. 1985; Pluss and Opal 1986; Pueringer et al. 1986; Ramani et al. 1991).

In 50 patients, a metabolic antigen was used to elicit delayed hypersensitivity skin reaction and delayed hypersensitivity skin reactions were positive in 78 percent and culture in 94 percent (Espinosa-Texis et al. 2001). Immunodiffusion has been positive in 80 percent, complement fixation in 40 percent and also Western blot has been performed (Arenas 2003)

Animal models of sporotrichosis have also provided data which suggest that acquired resistance to infections may occur. Experimentation has indicated that exposure of mice to viable cells of *S. schenckii* can confer increased resistance to a subsequent intravenous challenge with the fungus (Shiraishi et al. 1992). In addition, sensitized spleen cells which were transferred into fresh mice also conferred increased resistance to intravenous challenge. Further testing showed that T-cell-mediated macrophage activation led to increased killing of *S. schenckii* cells from a subsequent challenge, and conversely that pretreatment with a macrophage inhibitor reduced resistance to intravenous challenge. Other studies using the mouse model have also revealed that *S. schenckii* can secrete extracellular proteases, and that mouse antibodies formed against these enzymes correlate with the course of disease progression (Yoshiike et al. 1993). Furthermore, it has been shown, in the mouse model, that the cellular immune response becomes depressed between weeks 4 and 6 of infection, and is a harbinger of worsening disease (Carlos et al. 1992).

The infectivity of this fungus between isolates from human cutaneous and pulmonary sporotrichosis after subcutaneous injection into the footpad showed restricted fungal infection and, after intravenous or intraperitoneal injection of yeast forms, three of four isolates from cutaneous sporotrichosis were unable to establish infection, but the development of systemic infection was observed only with *S. schenckii* isolates obtained from the human lung lesion (Tachibana et al. 1999a)

The cell-mediated immune response against infection with *S. schenckii* has been investigated in vivo and in vitro. There have been few studies reporting the role of cytokines in this infection. In this study it was shown that immune lymph node cells expressed message for interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and interleukin-10 (IL-10) after stimulation

with heat-killed *S. schenckii*. These results suggest that acquired immunity against *S. schenckii* is expressed mainly by macrophages activated by CD4+ T cells, exerting protective immunity against *Sporothrix* via enhanced fungicidal activity (Tachibana et al. 1999b)

Differences in human serological response to sporotrichosis have been demonstrated for patients with cutaneous disease compared with patients with extracutaneous (joint, pulmonary, and CNS) disease (Scott and Muchmore 1989). In tests using a single strain of *S. schenckii* for antigen preparation, twice as many antibodies were detected in the sera of patients with extracutaneous infection. It is not clear how this may relate to pathogenicity, but the ability to detect antibodies that are specific for extracutaneous sporotrichosis could potentially provide a useful means for serological diagnosis of this complication.

Antibodies to *S. schenckii* antigens can routinely be detected in most cases of sporotrichosis through the use of complement fixation and latex agglutination tests, but such tests require the use of specialized, labile, and relatively expensive reagents. Therefore, as a practical matter, it is easier and cheaper to diagnose most infections by culture and microscopic examination of infected tissue. In the diagnosis of CNS sporotrichosis, however, detection of antibodies has succeeded in several patients when a culture-based diagnosis had failed. In such cases serological testing offers an invaluable tool (Scott et al. 1987).

A concanavalin A (conA)-binding fraction has been isolated from the *S. schenckii* cell wall (SsCBF) and the immunodominance of the *O*-glycosidically linked oligosaccharides in the reactivity of SsCBF with IgG from patients with sporotrichosis has been observed. These findings suggest that the SsCBF is a species-specific antigenic fraction recognized by human sera and with potential application in the serological diagnosis of sporotrichosis as well as in the epidemiologic survey of the systemic form of this mycosis (Loureiro et al. 2000).

A predominant antigen gp84 has been demonstrated by Western blot with a conA-horseradish peroxidase (HRP) conjugate (Lima and Lopes-Bezerra 1997)

LABORATORY DIAGNOSIS

The quickest means of diagnosing most mycoses is by immediate microscopic examination of infected host material. This approach is usually futile with sporotrichosis because the cells of *S. schenckii* normally occur very sparsely within infected material. However, painstaking histological examination of multiple tissue sections can often establish the diagnosis. Another approach to diagnosis by microscopy is the staining of histological tissue sections with a species-specific fluorescent antibody conjugate which can quickly provide a specific identification of *S. schenckii* (Kaplan and Gonzalez-Ochoa 1963); these fluorescent antibody reagents are, however, available only at certain reference laboratories and are not commercially offered. The usual form of *S. schenckii* in tissue is that of a yeast, but, in rare cases, superficial crusts from lesions or specimens from pulmonary infection have shown hyphal filaments (Maberry et al. 1966; Lopes et al. 1992).

By indirect immunofluorescence, parasite elements were demonstrated in 50 patients corresponding with a sensitivity and specificity of 100 percent. In this work indirect immunofluorescence was the most effective diagnostic method for sporotrichosis followed by culture, hypersensitivity skin reaction, and histopathology (Espinosa-Texis et al. 2001). It has been found that anti-*Sporothrix* antibodies are specific in sporotrichosis. Immunohistochemistry was performed in 25 paraffin-embedded biopsy specimens of sporotrichosis in which asteroid bodies (AB) were demostrated, ten of them with a positive culture. The AB were extracellular eosinophilic structures, 15–35 μm in diameter, and located within abscesses, with a central yeast. The yeast stains with the anti-*Sporothrix* antibody, while the spicules do not. Visualization of the spicules alone can lead to the demonstration of the AB in adjacent sections, and thus could be a useful clue in the diagnosis of sporotrichosis (Rodríguez and Sarmiento 1998). Immunohistochemistry has been a useful tool as is immunofluorescence when a yeast or AB is present (M. Heurre, personal communication) (Figure 8).

The most sensitive means of diagnosing sporotrichosis is recovery of the fungus in culture. Infected material is inoculated onto fungal culture media that are formulated to allow the growth of *S. schenckii* while selectively inhibiting the growth of fungal contaminants and the normal microbiota that could be present. Cutaneous specimens consist of pus or biopsied tissue from the lesion, whereas pulmonary specimens consist of expectorated sputum or material collected by means of a bronchoscope. If meningitis is suspected, cerebrospinal fluid is obtained for culture via a lumbar puncture. As cultures are often negative in cases of CNS infection, serological testing together with culture is recommended

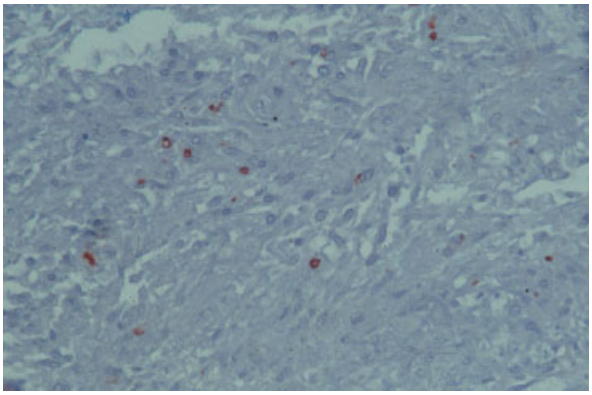

Figure 8 *Sensitivity by immunohistochemistry is as high as immunoflorescence for* Sporothrix *yeasts.*

(Scott et al. 1987). Serology should also be considered in any case where sporotrichosis is strongly suspected but cultures are negative.

MOLECULAR BIOLOGY

RFLP analysis of mitochondrial DNA (mtDNA) has been reported to be a useful method of identification, taxonomy, typing, and epidemiology of *S. schenckii*. Originally based on the phylogeny of 14 mtDNA types of *S. schenckii*, types 1–14 were constructed by estimating sequence divergences of mtDNA using restriction patterns with *Hae*III. Based on genetic distance, they have been clustered into two main groups: group A and group B. Isolates of group A exist mainly in North, South, and Central America, including Costa Rica (Ishizaki et al. 1996), and most of the Japanese isolates belong to group B (Takeda et al. 1991; Ishizaki et al. 1998)

S. schenckii strains have been classified into 23 types and clustered into two groups, group A and group B, on the basis of RFLP of mtDNA. The geographical distribution of mtDNA types was very characteristic. All isolates from Spain belonged to group B in contrast to North and South America where group A was predominant (Kawasaki et al. 2000) (Figure 9).

mtDNA types based on RFLP patterns with *Hae*III have been investigated also in China. In addition to types 1–23, a new mtDNA type (type 24) was found. Type 24 was divided into two subtypes (24A and 24B) based on RFLP with *Eco*RV. Seventy-seven isolates in China consisted of 58 isolates of type 4 (91 percent), five of type 6, one of type 5, one of type 20, and two of type 24, and classified into group A (types 1–3, 11, 14–19, 22 and 23) and group B (types 12, 13, 20, 21, and 24). Most isolates in China belong to group B and Korean isolates presumably belong to group B (Lin et al. 1999).

As we can see, group B contains most of the Japanese isolates and group A most of the American types. Group A is more branched compared with group B, where most of the types seem to be more closely genetically related and more mtDNA variability is found in group A, probably because the isolates have different geographic origins, although most of them come from the American continent. The molecular evolutionary explanations for the high variability are not clear. It will start to emerge with the molecular study of other genetic characters such as DNA sequences of mitochondrial and nuclear genes. mtDNA diversity was analyzed in 42 clinical isolates from Mexico, Guatemala, and Colombia, and six new types were found. Most of the strains belong to types 14 and 30, the former restricted

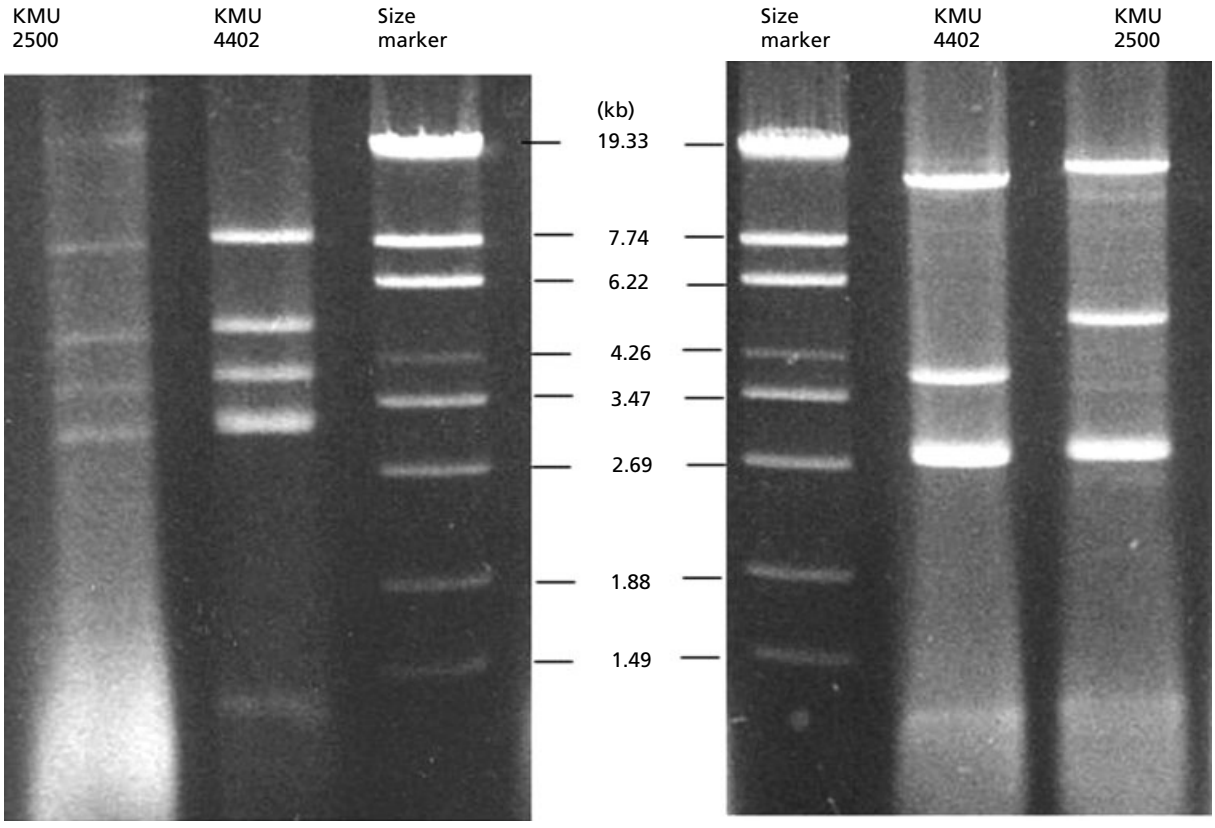

Figure 9 *RFLP patterns of mtDNA of* S. schenckii.

to Mexico, whereas the latter was distributed in Mexico, Guatemala, and Colombia. The new types (25–30) were identified in Mexico, Guatemala, and Colombia. These types were clustered in group A (types 26, 28–30) and group B (type 27). It seems that the variability in *S. schenckii* mtDNA is due in part to restriction site changes; however, the variation in size could also indicate length mutations (Mora-Cabrera et al. 2001).

Other clinical isolates were investigated for mtDNA type RFLP patterns with *Nae*III. The 62 isolates in South Africa comprised types 3 (9.7 percent), 4 (1.6 percent), 11 (9.7 percent), 17 (77.4 percent), and 23 (1.6 percent), whereas the 23 Australian isolates comprised types 3 (26 percent), 4 (56.5 percent), 7 (8.6 percent) and 21 (8.6 percent). The isolates in South Africa mainly belong to group A, with the predominance of type 17 (77 percent), and isolates in Australia mainly belong to group B.

The phylogenetic tree of mtDNA types and the worldwide distribution of types 3 and 4, suggest that these two types are ancestral types (or closely related), and that the others diverged from them over the course of continental drift. It may be that the divergence of mtDNA types occurred in South Africa earlier than in Australia (Ishizaki et al. 2000).

Partial cDNA cloning of a putative membrane transporter protein gene expressed in *S. schenckii* is reported and also DNA polymorphism of the isolated gene is demonstrated using polymerase chain reaction single-strand conformation polymorphism (PCR-SSCP) analysis. Also based on mtDNA diversity, *S. schenckii* has been classified into three groups located on the branches of the phylogenetic tree constructed by digestion profiles of mtDNA with restriction enzymes. The correlation of the results of PCR-SSCP analysis with the mtDNA diversity might indicate linkage of the mutation of the membrane transporter protein gene with the evolution of *S. schenckii*, and although the precise mechanism must be elucidated by further investigation, database searches also showed homology with the sugar transporter protein family (Sugita 2000)

Clinical isolates of fixed and lymphocutaneous forms from Mexico, Guatemala, and Colombia, as well as environmental isolates from Mexico, were studied by analyzing their phenotypic characteristics (conidial length, thermotolerance by percent growth inhibition at 35 and 37°C, median lethal dose (LD50), and genotypic characteristics [by random amplified polymorphic DNA (RAPD) analysis polymerase chain reaction (PCR)]. In general, the highest virulence, as determined by measurement of the LD50 for mice, was observed for the Mexican environmental isolates. *Sporothrix* fell into four major groups by hierarchical cluster analysis. A principal component analysis yielded three distinct groups, depending on the geographical origins of the isolates. This study revealed that isolates from Colombia had low thermotolerance at 35 and 37°C and could be associated with superficial skin lesions in patients with fixed clinical forms of sporotrichosis. Distinct patterns dependent on geographical origin were also revealed by RAPD analysis PCR, but these had no relation to the clinical form of the disease (Mesa-Arango et al. 2002).

TREATMENT

Uncomplicated lymphocutaneous sporotrichosis historically has been treated by oral administration of saturated solutions of potassium iodide, an inexpensive treatment that has proved effective in most patients. In some cases, the application of topical heat has been shown to cure lymphocutaneous disease (Hiruma et al. 1992b). A partial explanation for the efficacy of topical heat therapy has been provided by laboratory investigation. When yeast cells of *S. schenckii* were incubated in serum with polymorphonuclear neutrophils at 40°C as compared with 37°C, there was no difference in the rates at which the fungal cells were engulfed by the neutrophils. Once engulfed, however, the rate of killing by the neutrophils was significantly greater at 40°C than at 37°C (Hiruma and Kagawa 1986).

In one study of 58 patients, potassium iodide was equally effective whether administered once or three times daily, although side effects were slightly increased (Cabezas et al. 1996).

Potassium iodide cures approximately 90 percent of immunocompetent patients with sporotrichosis and relapses are rare. A pregnant woman taking excess quantities of iodine may result in possible goiter, hypothyroidism, and fetal death. Potassium iodide is currently a category D drug, meaning that it should not be used in pregnant or breastfeeding women unless the benefits of taking it outweigh the risks. Care must be taken in patients with renal failure and other potential causes of hyperkalemia, or in children with cystic fibrosis as they are susceptible to goitrogenic effects of iodide, or in patients with thyroid disease (Sanchez 2000; Sterling and Heymann 2000). Potassium iodide may cause the Wolff–Chaikoff effect (WCE), the cessation of thyroid hormone synthesis subsequent to the administration of iodide, but also iodine excess may lead to thyrotoxicosis (Jod–Basedow effect) and, rarely, iodine excess may cause an acute thyroiditis manifested by a painful, enlarged thyroid gland (Heymann 2000).

Modern antifungal compounds have been shown to be highly effective in curing lymphocutaneous sporotrichosis. Itraconazole and, to a lesser degree, fluconazole are orally administered drugs that are both effective; however, they are quite expensive and unavailable in many parts of the world (Sharkey-Mathis et al. 1993; Ghodi et al. 2000)

Forty-three Japanese cases of sporotrichosis were treated with itraconazole for 3 months, adult patients received 100 mg/day, whereas young patients under 5

years of age were treated with 50 mg/day; 88 percent have been assessed as cured or improved (Noguchi et al. 1999).

Terbinafine, another of the new antifungals, has been used topically for dermatophytosis, and preliminary results from oral use in cases of sporotrichosis have been promising (Hull and Vismer 1992).

A review article reported that 18 patients with sporotrichosis enrolled in five separate studies were cured by terbinafine at doses of 125–500 mg/day for a median of 12 weeks (range 4–37). They received terbinafine for up to 1 month after clinical resolution of lesions or for a maximum period of up to 6 months (Hay 1999; Pérez 1999). A total of 63 patients with cutaneous or lymphocutaneous sporotrichosis were randomized in a comparative study to evaluate the efficacy and safety of two doses of terbinafine, 28 were treated with 500 mg/day and 35 with 1 000 mg daily during a maximum of 24 weeks. Tolerance was similar in both groups, but 6 cases relapsed in the first group and none in the second. There were two drug adverse events related to the 1000 mg dose group, one case of gastrointestinal hemorrhage and one of progressive abdominal pain (Chapman et al. 2004).

Systemic forms including osteoarticular, pulmonary, and meningeal involvement can be life-threatening and very difficult to treat (Wescott et al. 1999).

Complicated cases of sporotrichosis are those that involve one or more joints, or that have disseminated to other organs, such as the CNS. These cases are very difficult to treat, and require the intravenous administration of amphotericin B. These patients may also need a prolonged subsequent regimen of an oral antifungal azole to prevent reactivation of the infection. In the case of AIDS patients, sporotrichosis (as with other fungal infections) can potentially be suppressed but cannot be cured, so lifelong suppressive antifungal therapy is required.

In patients infected with HIV, sporotrichosis may require systemic administration of amphotericin. The disease is potentially life-threatening. In one case amphotericin therapy was reinstituted but discontinued because of renal complications and amphotericin B lipid complex was then initiated at a dose of 5 mg/kg/day and was tolerated well, resulting in progressive resolution of all lesions. Lesions have recurred, despite the oral administration of itraconazole, fluconazole, or terbinafine. Blood levels of itraconazole are diminished by a number of agents that stimulate its hepatic metabolism, such as carbamazepine and rifampin (Ware et al. 1999) (see Table 1).

Differential diagnosis	4		

INTRODUCTION

The ability to form granules in vivo is a property possessed by a variety of microorganisms. Usually these granules are small, visible, microbial aggregates composed of cellular masses which are frequently filamentous. They probably represent the formation in vivo of colonies. However, their small size and the discrete nature of the granules are characteristic. The best examples are the 'grains' of a fungal mycetoma or eumycetoma and the sulphur granules of actinomycosis. A number of fungi produce clusters of hyphae in vivo, and these range in size from large fungus balls, which are easily visible in gross pathological material such as the aspergillomas, to dermatophytes, which can be visualized occasionally by microscopy within foreign body giant cells. Strictly speaking, these are not true granules and the nomenclature will be discussed briefly at the end of this section.

Mycetomas are chronic subcutaneous infections caused by fungi or actinomycetes (Table 1), known as eumycetomas and actinomycetomas respectively (Mahgoub and Murray 1973). The organisms are traumatically implanted into the deep dermis or subcutaneous tissue from the natural environment and cause a subcutaneous infection characterized by the formation of large aggregates of fungal or actinomycete filaments known as grains. A dense infiltrate of polymorphonuclear leukocytes and other inflammatory cells accumulates around these structures (Chandler and Watts 1987). This abscess either discharges onto the skin surface through draining sinuses or may involve contiguous structures such as the bone, causing chronic osteomyelitis. Mycetoma is a chronic disease process which causes considerable deformity and disability. It does not often spread beyond the locality of the initial site of infection and is seldom fatal. As there are pronounced differences in the treatment and prognosis of mycetomas resulting from different organisms, in particular between the eumycetomas and actinomycetomas, identification of the causative organisms plays a key part in their management.

The name mycetoma has been applied erroneously to a number of other conditions including those in which a large fungus ball is formed and dermatophyte pseudomycetomas (Ajello et al. 1980). The formation of a fungus ball, exemplified by the disease aspergilloma, usually occurs within a cavity formed as a result of disease. Lung cavities are most often affected although fungus balls may occur in the paranasal sinuses. The fungi find their way to this site either through inhalation or bloodstream spread, but not through implantation. Sinuses affecting the skin are not formed and the pathogenesis of this form of fungal infection is different from that of a true mycetoma. Dermatophytes may produce granules composed of mycelial elements which often develop within giant cells (Ajello et al. 1980). Once again, the pathogenesis is completely different from mycetoma. Infections do not follow implantation of environmental organisms but follow invasion from a site

a) Very rare causes of mycetoma.

on the skin, particularly the hair follicle. For this reason granules formed by dermatophytes are sometimes referred to as pseudomycetomas.

HISTORY

Mycetoma, Madura foot, is a disease of great antiquity and was probably known by the ancient Indian writers as padavalmita (foot anthill) (Sran et al. 1972). Changes suggestive of mycetoma have also been found in ancient skeletal remains in Israel (Spigelman and Donoghue 2001). The earliest medical description of the condition in Western literature appears to be that of the German traveller and physician, Kaempfer (1651–1716) and formed part of his doctoral thesis at the University of Leyden in Holland in 1694 (Kaempfer 1694). The thesis, 'Disputatio physica medica inauguralis exhibens decadem observationum', contains a section concerned with a disease called 'Perical' or 'ulcerous hypersarcosis of the feet' which was indigenous to Malabar in southern India. He described a tumorous disease generally affecting the feet which, as a result, would enlarge to three or four times the normal size. A feature of the condition was said to be the presence of oozing and granules. However, it was not fatal and caused considerable deformity often as a result of treatment – generally caustics or the application of heated metal. In 1842, Gill, an English surgeon working in the Madurai dispensary, once again in southern India, was said to have mentioned a condition that may have been mycetoma in a dispensary report (Gill 1842, cited in Carter 1874). The disease was first described in the medical literature by Godfrey (1846), who was the garrison surgeon in Bellary, Madras, India. He described four patients and his paper was published in *The Lancet* entitled 'Diseases of the foot not hitherto described.' Godfrey reported this new condition as 'morbus tuberculosis pedis' and the gross deformity, but non-fatal nature, of the condition was emphasized (Godfrey 1846). In 1859, Eyre drew attention once again to the small characteristic pigmented specks seen within mycetomas and mentioned in Kaempfer's original article (Eyre 1859). Originally these were thought to be caused by blood, but their presence was noted to be a characteristic of this particular infection. Although many cases involved the feet, other sites were also affected; for instance, Minas (1860) first described lesions of the hand and pointed out that the grains in lesions could be either black or pale but that the former were more common. The bone changes were first described by Ballingali (1855).

The causative organisms were first described in 1860 by Carter who suggested that the small bodies were 'fungus particles.' He also proposed that these were fungi of plant origin (Carter 1861). He believed that the white particles or grains were merely degenerate elements of the black form. In order to clarify the etiology of mycetoma, Carter enlisted the help of the Reverend Berkley who isolated a red mold from a lesion. Berkeley named this fungus *Chionyphe carteri*, a new species (Berkley 1862). The true identification of this organism remains unknown as it does not correspond to any fungus recognized as pathogenic today. In 1874, Carter produced a monograph on mycetoma, 'On mycetoma or the fungus disease of India,' using this disease name for the first time (Carter 1874). He also appears to have described the pathological features of an infection caused by the organism now known as *Madurella mycetomatis*. The first isolation of a fungal species recognized today was by Brumpt (1906), who cultured the organism *Madurella mycetomi (-atis)*, from a black grain infection.

The pathogenesis of mycetoma still eluded investigators. For instance, Bidie also carried out detailed studies of the disease in Bombay and studied the grains which he also believed to be caused by fungi that had entered the body as spores (Bidie 1862). However, the most likely explanation for the true portal of entry of organisms came in 1893, when Bocarro found a thorn embedded in the inflammatory mass and proposed that the infection was usually introduced by a minor injury (Bocarro 1893). Although until this time most of the cases originated from India, it soon became clear that cases were being reported from Algeria, the USA, and Sudan.

In 1894, two observations showed that actinomycetes were also causes of this infection. Boyce and Surveyor (1894) observed that the size of filaments within certain grains of mycetomas were fine and more likely to be bacterial in origin. In the same year, Vincent (1894) isolated an organism that he named *Streptothrix madurae* (probably *Actinomadura madurae*) from an Algerian case.

PATHOGENESIS

A unifying theory for the pathogenesis of mycetoma is hampered by the lack of an effective animal model for

eumycetomas, although there are experimental models for actinomycete infections such as nocardiosis (mice) and *A. madurae* (goats). However, there is evidence to connect mycetoma with implantation of microorganisms from the environment coupled with an extraordinary series of adaptive mechanisms which are of potential benefit to the survival of the organisms in nature.

Some of the causative fungi have been isolated from the natural environment. For instance, *Leptosphaeria senegalensis* has been identified in the natural environment in acacia thorns (Segretain and Mariat 1969). In addition, it is occasionally possible to see plant material, probably originating from a thorn in some lesions of mycetoma (Cameron et al. 1973). These appear as pieces of lignified tissue containing fungal hyphae. Basset and co-workers removed thorn material from two cases and cultured *L. senegalensis* from one and *Pyrenochaeta romeroi* from the other (Basset et al. 1965).

There is no evidence to suggest that the infection is specifically associated with an underlying host predisposition and, even though some patients appear to have defective T-lymphocyte-mediated responses to the fungi, these have been described in those with extensive disease, suggesting that they may have followed rather than caused the infection (Mahgoub et al. 1978). Other investigators have failed to find any changes in T-lymphocyte function in patients with disease (Bender et al. 1987). There is also nothing to suggest that other less debilitating changes in immune function occur in mycetoma patients, although in one study a high frequency of diabetes mellitus was reported among patients (Hay and Mackenzie 1983). The rare cases reported in immunosuppressed patients may even be atypical with the formation of clusters of hyphae rather than frank grains (Meis et al. 2000) This has also not been mentioned by others (Mahgoub and Murray 1973). By contrast, there is evidence that fungi in mycetomas may develop a number of different adaptive changes in vivo, such as cell wall reduplication or unfolding of the cytoskeleton, or deposition of extra- or intracellular melanin, all of which may affect the ability of the host inflammatory response to destroy the organisms. Cell wall reduplication gives rise to an 'onion skin' appearance around cells in eumycetoma grains caused by different species under electron microscopic examination (Hay and Collins 1983; Wethered et al. 1987). This appears to follow intrahyphal growth of mycelial elements. Adjacent cell walls also fuse, particularly at the rim of the grain where, in addition, there is evidence of deposition of human immunoglobulin. The contribution of the latter to the microstructure of grains is unknown. In the case of *M. mycetomatis*, cells within the grain may be surrounded by electron-dense homogeneous material, fungal melanin. This is very resilient to physical extremes and is difficult to section using a microtome (Findlay and Vismer 1987). Once again it is thought to provide a protection for living cells within the fungal grain.

As yet there is little evidence among the fungal causes of mycetoma of immunomodulation as has been demonstrated with the actinomycete, *Streptomyces somaliensis*, which produces an extracellular protease that affects the ability of macrophages in vitro to kill bacteria (Nasher et al. 1987).

EPIDEMIOLOGY

The epidemiology of the geographical distribution of cases of mycetoma is well documented. As a result of a worldwide postal survey, Mariat (1963) produced evidence that mycetomas were found throughout a range of countries, mainly confined to tropical regions, and that infections outside these areas were rare and usually occurred as imported infections. The countries reporting the highest prevalence of infection were Mexico where *Nocardia brasiliensis* was the dominant organism and Senegal where most infections were caused by fungi. In addition to these countries, India and Sudan have a higher than average prevalence of infection (Mahgoub and Murray 1973; Hay et al. 1992). In these two areas, *M. mycetomatis* is the most common reported cause of mycetoma. *Nocardia* spp. and *M. mycetomatis* were also the most common organisms documented in the Mariat survey, accounting for 32 and 19 percent of the total, respectively. Recently, *M. mycetomatis* DNA has been identified in soil (23 percent) and thorn (5 percent) samples from Sudan but not from the Netherlands (Ahmed et al. 2002). In addition, mycetomas occur throughout central and northern South America, around the Saharan region and Central and South Africa, the Middle East, India, and Pakistan. Infections are less frequently seen further east. The main endemic areas for mycetomas are relatively arid and have a short rainy season, with a constant temperature with little fluctuation with different seasons or at night (Gonzalez-Ochoa 1962). In temperate areas, mycetoma infections are rare and usually caused by fungi rather than actinomycetes. There are reasons for suspecting the accuracy of some of these data. In the UK, for instance, over half the fungal causes of imported mycetomas resulted from pigmented fungi that are sterile and produce nonpigmented grains in vivo (Hay and Mackenzie 1983). They cannot therefore be assigned to a single species or genus. There is evidence from the analysis of the protein profiles of some of these agents, which appear to be very similar in gross morphology, using polyacrylamide gels, that this is a heterogeneous group of fungi (Zaini et al. 1991).

There are variations within the endemic areas although these principally affect the actinomycetes where, for instance, *S. somaliensis* is mainly found in hot and dry climates with less than 50–250 mm of rain per

year. Among the fungi, *Pyrenochaeta romeroi* is also found in areas with higher rainfall levels (Mahgoub and Murray 1973). As has been described above, the fungi that cause mycetomas are associated with vegetation such as acacia trees (Segretain and Mariat 1969). This is compatible with the description of the endemic areas because they are mainly seen in regions with low rainfall.

Mycetoma is most often seen in men, the male:female ratio of infections being approximately 4:1. It is mainly a disease of rural workers aged between 16 and 45 years. Although they may not give a history of an initiating trauma, their occupation predisposes to such an event. Women with mycetomas are also usually from rural areas and work in the fields. However, occasionally mycetomas are found in nonmanual workers.

CLINICAL APPEARANCES

The clinical appearances of mycetoma are characteristic (Abbott 1956; Mahgoub and Murray 1973). The incubation period is unknown as most patients do not give a history of a trauma that initiated the lesions. However, in some cases, it is clear that infection started over 8 years after a traumatic injury (Maiti et al. 2002).

The earliest sign of a mycetoma is the appearance of a hard subcutaneous nodule (Figure 1). This is painless and usually found on exposed sites such as the arms and legs. More than 95 percent of mycetomas start at these areas. As the lesion enlarges, sinuses appear on the skin surface (Figure 2). These present as papules 0.2–0.5 cm in diameter or pustules that discharge their contents and then dry up, leaving a small scar. Sometimes individual lesions are painful before the release of purulent material. At an early stage, pain and tenderness are intermittent and unpredictable. As the lesion increases in size, the whole area becomes hard, swollen, and, in time, limbs become grossly deformed. In advanced mycetomas there is often localized sweating over lesions (R.J. Hay, personal observation). In some cases pain becomes prominent in the later stages, but conversely, patients may have very extensive lesions without symptoms.

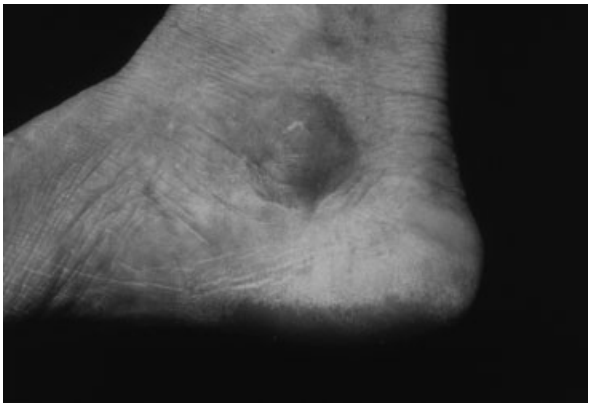

Figure 1 *Early mycetoma before the development of sinuses*

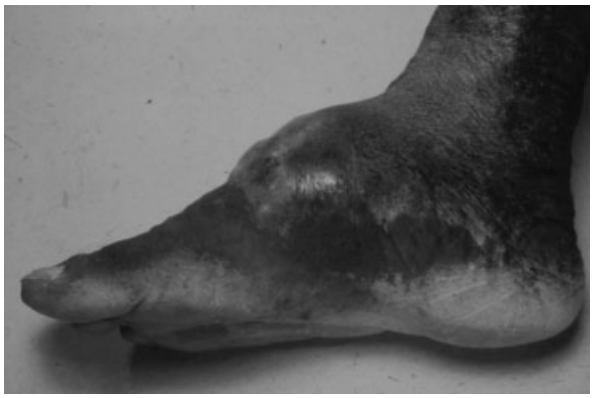

Figure 2 *Mycetoma of the foot caused by* Madurella grisea

Occasionally mycetomas may be found on the scalp and thorax, although these are most often caused by actinomycetes, namely *S. somaliensis* and *Nocardia* spp., respectively. It is not possible to distinguish clinically with any degree of certainty between the different causes of mycetoma. The lesions usually remain localized and are locally aggressive. Actinomycetomas usually evolve more rapidly than eumycetomas, but this cannot be relied on as a means of distinguishing between the two types. Very rarely, lesions may spread to lymph nodes, although this is most likely to occur with *S. somaliensis* (El Hassan and Mahgoub 1972). Metastatic mycetomas are exceptionally rare and, on the few occasions where two lesions are seen, these may have been caused by separate infections. Occasionally cystic mycetomas confined to the bone and without draining sinuses have been described (Fahal et al. 1998). The main complications of eumycetomas are deformity which can lead to considerable disability, fungal osteomyelitis, and secondary bacterial infection. The last is not common but may cause an acute exacerbation of the swelling and increased purulent discharge from sinuses combined with pyrexia.

DIFFERENTIAL DIAGNOSIS

Mycetoma must be distinguished from other conditions in which draining sinuses may develop. These include actinomycosis which is usually restricted to sites where the causative organisms are carried, such as the mouth and jaw. The grains in actinomycosis are soft and yellowish. Botryomycosis, a bacterial disease, may also be confused with mycetoma, although there is usually wider internal spread and patients have a pronounced fever. Carcinomas, such as squamous carcinomas, chondrosarcoma, and Kaposi's sarcoma, may have to be distinguished where necessary by biopsy.

Diagnostic imaging

The radiological appearances of mycetomas are well described (Davies 1958; Cockshott 1968). They include soft tissue swelling, endosteal cavitation with small cystic lesions, and periosteal bone erosion (Figure 3). New bone growth is often seen in longstanding lesions along the periosteum. Hyperostosis may occur in the skull and other areas and, in advanced lesions, pathological fractures and bone resorption can be seen. Once again it is difficult to distinguish between eumycetomas and actinomycetomas. Cystic lesions are often fewer and larger in eumycetomas. Other methods of detection include bone scanning and echo scanning. Bone scans may be more useful at detecting early bone involvement than x-rays, although not widely available in the endemic areas. Ultrasound scans show the marked tissue and bone swelling with hyperreflective areas (Fahal et al. 1997). However, magnetic resonance imaging provides a clearer picture of both bone and soft tissue distribution (Czechowski et al. 2001)

Laboratory diagnosis

The diagnosis of eumycetoma is confirmed by the demonstration of grains in lesions and their identification. This is important in order to provide information on prognosis and treatment. For instance, it is important to differentiate eumycetomas, which often respond poorly to chemotherapy, from actinomycetomas, which respond well. In addition, there are differences in responses within the eumycetomas. Infections caused by *M. mycetomatis* respond to ketoconazole in about 50 percent of cases. Likewise, it is worth using intravenous miconazole in infections caused by *Scedosporium apiospermum*.

The methods of laboratory diagnosis of granule-forming fungi are no different from those used for other fungal infections: direct microscopy, culture, serology, and histopathology. The key to the diagnostic process is the extraction of grains from lesions. This can be accomplished in one of two ways.

First, an unruptured pustule is identified, cleaned with an alcohol swab and gently pierced with a sterile needle. The edges of the sinus beneath are squeezed, and a small drop of pus and blood is extruded. This is then spread on a glass slide where it is possible to identify small (200 μm to 2 mm) granules that are white/yellow, black, or red. These are then processed for microscopy, culture, and histopathology (see section on Histopathology below). Often it is necessary to open more than one pustule and it is important to scrape beneath the edge of the scab because grains may be trapped there.

Deep biopsy is the second approach. A superficial biopsy removing the mouth of a sinus track is seldom effective because the amount of material is usually insufficient to identify grains, and the chances of the specimen containing a grain are low because the mouth of the sinus merely represents a pathological thoroughfare. A large deep biopsy, which is usually taken under a general anaesthetic, on the other hand, provides a large amount of material from which it may be possible to identify grains. These should be picked out of the tissue for culture and for histopathology – segments containing visible grains should be sent for processing.

Fine needle aspiration can also sometimes provide suitable diagnostic material (El Hag et al. 1996)

Direct microscopy

Grains are mounted in 5–10 percent potassium hydroxide and allowed to stand for 1–2 hours. The material is then gently flattened by pressure on the cover slip. Grains must be distinguished from clusters of neutrophils, but it is possible to make out their structure using this method, as well as the type of pigmentation. Extracellular melanin produced by *M. mycetomatis*, for instance, forms into irregular clusters of pigmentation. The presence of hyphae in grains can be seen under high power objective (Figure 4). If broad hyphae are not seen, it is likely that the grain is caused by an actinomycete.

Culture

Provided the appropriate material is selected, culture is usually successful. It is best to use conventional media such as Sabouraud's agar for primary isolation, using plates or tubes both with and without antibiotics such as penicillin and streptomycin (Mahgoub and Murray 1973; Mariat et al. 1977). The rate of growth is highly variable and therefore cultures should be kept for at least 3 weeks before they are discarded as negative.

The criteria for recognition are no different from those used with other fungi. Colonial morphology, patterns of sporulation, pigmentation, and growth rates

Figure 3 *X-ray of eumycetoma of foot caused by a* Fusarium *species*

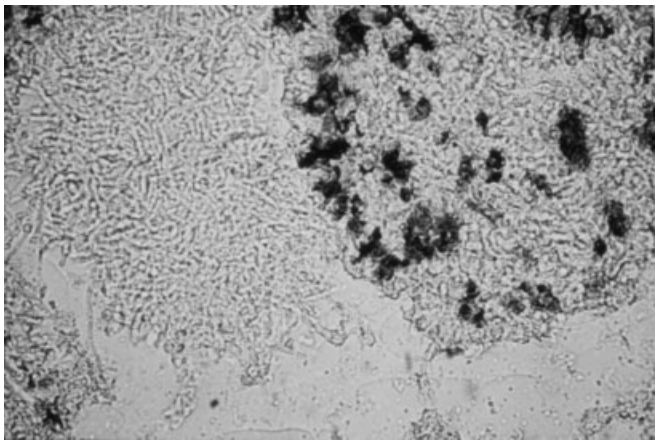

Figure 4 *Grains of* Madurella grisea. *Magnification × 300; stain: KOH mount.*

are all important. Media used range from Sabouraud's to Czapek–Dox or Lactrimel (Borelli and Feo 1966). Failure to sporulate is common and a variety of media should be used. The main means of diagnosis is through colonial characteristics. However, some physiological tests have been carried out on the more common mycetoma agents (Table 2).

At present there are few studies and no established molecular diagnostic tests although these have been applied to certain organisms, notably *M. mycetomatis* (Lopes et al. 2000). The cultural characteristics of the main organisms are discussed below

ACREMONIUM SPECIES

Most of these fungi implicated in mycetoma were previously described as members of the genus *Cephalosporium*. The main species implicated in mycetoma are *Acremonium kiliense*, *Acremonium falciforme*, and *Acremonium recifei*. Colonies of all three are slow growing and downy. The color is white to pink. On the undersurface there is usually a clear pigmentation that is pink to rose in color. The hyphae are not pigmented. Conidia are borne on aerial hyphae and appear in clusters bound by a gelatinous material. These conidia are single or multicellular and fusiform with a slight curve; some conidia appear as a shallow crescent. They are about 10 × 4 μm in length and width. The different species vary in conidial structure.

A. falciforme is mainly crescentic and nonseptate, but has some two- or three-celled conidia; *A. kiliense* has straight short conidia; *A. recifei* is mainly crescentic and nonseptate.

EXOPHIALA JEANSELMEI

Previously known as *Torula*, *Pullularia*, or *Phialophora jeanselemi*, this fungus forms a distinct colony that changes with time from a predominance of yeast-like cells, which form a glabrous mucoid colony with dark pigmentation, to a downy colony containing a lot of mycelium with aerial hyphae. Conidia are produced by annellation. These are formed and are often seen in clusters at the tip of an annelide. Conidia are oval and about 5 × 1 μm in size (Nielsen et al. 1968).

LEPTOSPHAERIA SPECIES

These fungi can be recognized by their more rapid growth to produce a downy colony with a gray to black reverse pigmentation. With *L. senegalensis*, asci are produced on older colonies and these contain eight oval ascospores that are long, measuring up to 30 μm in length. The ascospores of *Leptosphaeria tompkinsii* are shorter.

MADURELLA SPECIES

M. mycetomatis has other generic synonyms such as *Streptothrix* and *Glenospora*, as well as other *Madurella*

Table 2 *Physiological characteristics of common fungal causes of mycetoma*

Species	Starch	Gelatin	Glucose	Galactose	Lactose	Maltose	Sucrose
Scedosporium apiospermum	+	+	+	var	–	–	var
Madurella mycetomatis	+	±	+	+	+	+	–
Madurella grisea	+	–	+	+	–	+	+
Pyrenochaeta romeroi	+	±	+	+	–	+	+
Leptosphaeria senegalensis	+	?	+	+	var	+	+
Exophiala jeanselmei	–	–	+	+	–	+	+

species. It was originally named as *M. mycetomi* but this was subsequently changed to the form used today: *M. mycetomatis*.

The rate of growth of *M. mycetomatis* colonies is very variable, but may start very slowly. Colonies are often glabrous initially and of a white to tan color, with deep folds that develop a down, resulting from hyphal proliferation over the surface. This is cream to gray in color. Diffusible brown pigment can be seen on the undersurface. Conidial formation is best seen on cornmeal agar. *M. mycetomatis* produces either small flask-like phialides which produce small round conidia (2–4 μm in diameter) or elongated pyriform conidia (3–5 μm). In old colonies there are numerous black sclerotia 1 mm in diameter.

Madurella grisea

The colonies are similar to *M. mycetomatis* initially, although there is no diffusible pigment. Once again a small downy cover forms after 2–3 weeks. Colonies are sterile, although on poor media pycnidia form. Recognition is difficult as the fungus is sterile and some concern has been expressed that isolates identified as *M. grisea* may not form a single species. Protein patterns analyzed from extracted fungi by polyacrylamide gels suggest that their protein patterns are not homogeneous. At present there have been no published studies that employed genetic techniques to compare different isolates.

NEOTESTUDINA ROSATII

This was formerly named *Zopfia rosatii*. The organism produces a slow-growing yellow to brown-colored colony which is covered by folds. On certain media such as cornmeal agar older colonies (after 3 weeks) produce asci. The ascostromas are easily distinguished because of their black color. Asci are long, up to 30 μm, and have thick walls; they contain eight two-celled ascospores which are 10 μm in length (Segretain and Destombes 1961).

PYRENOCHAETA SPECIES

P. romeroi produces a dark downy colony with a black to tan undersurface. The colony expands rapidly and produces pycnidia. These have thick outer walls with setae. Pycnidia are 40–100 μm by 50–120 μm in size and contain elliptical and yellowish pycnidiospores which are about 1 μm in diameter. These are produced by phialides in chains. A new species, *Pyrenochaeta mackinnonii*, differs in the size of pycnidia and pycnidiospores (Borelli 1976).

SCEDOSPORIUM APIOSPERMUM

This fungus is the imperfect state of *Pseudallescheria boydii*. It is synonymous with *Monosporium apiospermum*. The colonies are rapidly growing and a lot of fluffy aerial mycelium is produced which is white at first, but with time becomes gray or brown. The underside of the culture is usually gray. Sectoring or contour formation may occur on the colonial surface. Conidia are produced singly or in clusters on anellophores or laterally on conidiogenous hyphae. These conidia are distinctive, large, lemon-shaped and with a yellowish color. They vary from 4–9 to 6–10 μm in size. Some colonies produce asci. The ascospores are lightly pigmented and round to oblong (6 × 6 μm).

The isolation of unusual organisms

The other fungal causes of mycetoma are very rare and have been described on a single or, at the most, two occasions. It is difficult to decide whether an isolated organism is a novel cause of mycetoma or a contaminant. Theoretically, as most of these agents are of low virulence, it is possible for other environmental organisms to be implicated in mycetomas. If the organism is isolated at least twice from grains, and these are compatible with a fungal infection, it is likely that they are the cause of the infection. Such rare organisms include *Pseudochaetosphaeronema larense* (*Chaetosphaeronema larense*) (Borelli and Zamora 1973), *Cylindrocarpon (Phialophora) cyanescens* (Zoutman and Sigler 1991), *Phialophora parasitica* (Pracharktam et al. 2000), and *Pyrenochaeta mackinnonii* (Borelli 1976). Other fungi described as causes of eumycetoma are *Corynespora cassiicola* and *Plenodomus avramii*.

Serodiagnosis

The value of serodiagnosis in the diagnosis of mycetomas is debatable. Certainly it cannot be used as a screening process for suspicious-looking lesions, given that weak positive reactions may occur in otherwise healthy individuals. There are also no commercial systems for the detection of antibody or antigen in mycetoma.

The techniques used have generally depended on either immunodiffusion or counterimmunoelectrophoresis (Murray and Mahgoub 1968; Mariat et al. 1977); there is no enzyme-linked diagnostic system such as an enzyme-linked immunosorbent assay (ELISA), which has been developed specifically for measuring antibodies to mycetoma as a diagnostic measure, even though investigators have used ELISA to study the pathogenesis of infection (Wethered et al. 1988). An immunodiffusion assay has been established in a few laboratories and provides useful help for following the course of treatment where initial reactions are strongly positive. This is more often seen with actinomycetes such as *Nocardia* spp. or *S. somaliensis* (Murray and Mahgoub 1968). Both these groups give strongly positive responses which can be quantitated and followed as a guide to treatment outcome or relapse. Generally, for most eumycetomas, the serological responses are less

reliable and their monitoring only occasionally forms a useful part of the management of these infections.

HISTOPATHOLOGY

Provided that the limitations of histopathology in the diagnosis of mycetoma are recognized, this is a useful procedure. It can be performed either on grains extracted from lesions and fixed immediately in formalin or on biopsy material. If grains are used, it is important to ensure that the laboratory staff can also identify the relevant material in the specimen pot, otherwise it will be discarded. For most purposes, recognition is based on the appearances of grains using the hematoxylin and eosin (H&E) stain (Winslow and Steen 1964; Mahgoub and Murray 1973; Mariat et al. 1977; Destombes 1978; Chandler and Watts 1987). Specific fungal stains such as the methenamine silver and periodic acid–Schiff (PAS) stains are useful to ensure that fungi are present, but are seldom helpful for specific diagnosis. Actinomycete filaments also take up silver-based stains.

A scheme for the identification of mycetomas is shown in Table 3. The key elements for recognition are the presence of pigmentation and whether it is intramural or extracellular, the size and shape of grains, and their affinity for H&E. Although, with practice, it is possible to separate some of the black grain eumycetomas by their appearances in H&E, this is not the case with pale grain fungi. There is some evidence that infections caused by *S. apiospermum* show clusters of vesicular expansion of hyphae at the grain periphery and that this is less common with other nonpigmented agents of mycetoma (Figure 5). However, this is not completely reliable as a means of distinguishing among different organisms. The definitive diagnosis is made by culture.

Dermatophyte hyphal clusters are often referred to as pseudomycetomas. They seldom produce sinuses, but clusters of fungal hyphae are seen in giant cells in the dermis rather than subcutaneous fat or fascia (Chandler and Watts 1987). This mode of pathogenesis is somewhat similar to that seen with *S. somaliensis* which also starts as an intracellular infection (Nasher et al. 1987). However, with dermatophytes, the fungal hyphae are discrete and unaltered, in contrast to those seen with other fungi, where there are gross cell wall changes. They also originate from an endogenous infection and are not implanted from the environment. In some cases, pseudomycetoma caused by dermatophytes appears to follow persistent hair shaft infection whereas, in others, it is a manifestation of disseminated subcutaneous disease. Both types are rare.

Electron microscopy does not play a role in the diagnosis of mycetomas although it is useful for studying the pathogenesis of infection. As described above, a characteristic of these infections is the change in cell wall structure with gross thickening and fusion of adjacent cells. The cell walls often show an 'onion skin' appearance, which is probably the result of intrahyphal growth of fungi (Hay and Collins 1983).

Immunofluorescence has not been developed as a means of identification of mycetomas. This is partly the result of autofluorescence of grains which makes recognition difficult. Theoretically there is no reason why nonfluorescent techniques, such as immunoperoxidase staining, should not be used for mycetomas as there is no evidence that there is antigenic variation in vitro versus in vivo that could lead to false-negative reactions. However, reagents for such tests are not available at present. Likewise there is no established place for molecular genetic techniques such as Southern hybridization or restrictive fragment length polymorphism (RFLP) analysis in the diagnosis of these infections.

Table 3 *Characteristics of the grains of the common eumycetoma agents*

Color	Species	Size (μm)	Shape	Appearances in H&E[a]
White (pale)	*Scedosporium apiospermum*	500–1500	Irregular	Prominent vesicles. Round–oval Eosinophilic fringe
	Neotestudina rosatii	500–1000	Regular oval or round, lobed	Compact with cement-like matrix, basophilic hyphae
	Acremonium or *Fusarium* spp.	500–2000	Regular oval or round	Dense packing of hyphae which stain poorly
	Aspergillus nidulans	200–1000	Lobed	Pale, poor staining of fungal hyphae, hyaline
Black	*Madurella mycetomatis*	500–5000	Irregular lobed	Hard, cement-like matrix Hyphae swollen and indistinct
	Madurella grisea	500–2000	Irregular	No cement, swollen hyphae Individual elements distinct
	Leptosphaeria senegalensis	500–2000	Arc-like. Round	Distinct hyphal rim, diffuse central hyphae
	Exophiala jeanselmei	200–1000	Arc-like	Dense hyphal rim, neutrophil invasion common

a) These appearances are features described in H&E stained sections. They are variable.

TREATMENT

Treatment of eumycetomas with chemotherapy is difficult and their management often involves deciding from conservative approaches involving observation, a trial of chemotherapy, and surgery (Hay et al. 1992).

Conservative management

Eumycetomas are seldom life-threatening and are often asymptomatic. Where chemotherapy is not available, it may be preferable to review patients regularly without active intervention. Relief of pain and dressings to sinuses may be required from time to time.

Chemotherapy

The range of antifungals that can used with success in mycetomas is not great. In some cases, responses have been seen with amphotericin B, either in conventional formulation or in combination with lipids or liposomes; ketoconazole may also be effective. Reports of individual successes with itraconazole and terbinafine have been recorded, although in no case has there been sufficient follow-up to establish cure (Paugam et al. 1997; Hay 1999). Of all these approaches, more is known about ketoconazole, which in daily doses of 200 mg has been recorded as a successful therapy for mycetomas caused by *M. mycetomatis*. The response rate is variable though and probably depends on the extent of the infection, but in about half the cases successful results can be obtained. Therapy is continued for at least 3 months and 12–18 months may be required. In other patients a trial of therapy is a wise choice as this can be guided by the in vitro sensitivity pattern [minimal inhibitory concentration (MIC)] of the organism isolated. Although this approach has some logic, in vitro sensitivity is not a good guide to cure or remission and it is probably more realistic to regard this approach as palliative in slowing enlargement of lesions. As such, it has clinical value even though it is seldom curative. Griseofulvin is seldom active against mycetoma agents in vitro and yet it appears to slow the progress of mycetomas in some patients. It is possible that this is because it is an active inhibitor of leukocyte chemotaxis and suppresses the accumulation of neutrophils in lesions (Yousef and Hay 1987).

There is no published experience on the use of immunological therapy such as cytokines – granulocyte–macrophage colony-stimulating factors – in mycetoma.

Surgery

The ultimate method of eradicating a fungal mycetoma is surgical excision (Mahgoub and Murray 1973). However, it is important to recognize that this has to be sufficiently radical to ensure an adequate margin of excision, otherwise relapse is inevitable. Local excision of mycetomas on the foot may cause practical problems if there is insufficient tissue remaining to allow adequate weight-bearing support, and pain on standing or walking may result. In other words, the extent and method used have to be considered carefully. The definitive curative process is adequate amputation, again ensuring that the margins are well clear of infected bone or subcutaneous tissue. Amputation has to be carefully considered together with the patient, taking into consideration the site, the resulting disability and its effect on employment or social life, the availability of good prostheses, and the discomfort or deformity caused by the lesion. In many cases this may be the best approach, but it should be arrived at after proper consideration of all the alternatives and after informed discussion with the patient. It may be preferable to accept a measure of disability with an untreated mycetoma if the alternative is an operation that would deprive the patient of his or her livelihood.

APPARENT GRANULE FORMATION BY OTHER FUNGI

In addition to mycetomas, granule-like structures may be formed by a number of different organisms in vivo. Usually this is a pathological phenomenon and not seen normally with infections caused by these organisms. The exception is where mycelial fungi grow within spaces or cavities such as pathological cavities in the lung. Under these conditions a number of different fungal species produce a fungus ball. *Aspergillus* spp. are the most common causes, but other organisms from *Coccidioides immitis* to *Pseudallescheria boydii* have been implicated and it is possible that all mycelial fungi have the propensity to form into balls given the appropriate conditions in vivo. However, two specific and different examples of in vivo granule formation are seen with the dermatophytes and *Scedosporium apiospermum*.

Pseudomycetomas caused by dermatophytes

These have been defined in the Introduction. As their pathogenesis is completely different to that seen with mycetomas, they are termed 'pseudomycetomas' (Ajello et al. 1980). The aggregates are formed of loose collections of dermatophyte mycelium, usually packed into giant cells. This phenomenon has been seen after hair shaft infections caused by both endothrix and ectothrix pathogens; it may also occur in the rare disseminated forms of dermatophytosis.

Strictly speaking, these collections are randomly aggregated hyphae and are not granules at all.

Systemic infections caused by *Pseudallescheria boydii* (*Scedosporium apiospermum*)

This organism is a known cause of mycetoma. Occasionally the rare systemic infections caused by this organism produce a compact aggregate of hyphae like a microcolony. This cannot be distinguished as a 'granule' in gross pathological specimens and is once again best designated as a pseudogranule.

Protothecosis

R. SCOTT PORE

Etiologic agents	1	Host responses	2
History	1	Laboratory diagnosis	7
Epidemiology	1	References	13

ETIOLOGIC AGENTS

The etiologic agents of protothecosis are algae:

- *Prototheca wickerhamii* Tubaki and Soneda 1959
- *Prototheca zopfii* Krüger 1894
- *Chlorella* spp. Beyerinck 1890 may cause infections.

HISTORY

Prototheca spp. were discovered by Zopf (Krüger 1894a, b) and are related to *Chlorella* spp. Species of both genera reproduce only asexually by similar internal formation and subsequent release of spheroidal progeny cells from a parental sporangium. Species of both genera can subsist saprophytically in wastewater (Pore 1983). Comparison of nutritional and cell wall composition data has led to a proposed phylogenetic relationship between the chlorophyll-free *P. wickerhamii* and the photosynthetic *Chlorella protothecoides* Krüger (Pore 1972; Conte and Pore 1973). Confirmation of this relationship came from DNA base composition data (Huss et al. 1988), and sequence similarities between the 16S-like ribosomal RNA (rRNA) and the genetic DNA that separated these two species from the other *Chlorella* spp. tested (Huss and Sogin 1990). On the one hand, *Chlorella* spp. are polyphyletic, but DNA-binding homologies showed heterogeneity among *Prototheca* spp. as well (Huss et al. 1988). Although it has been postulated that *Prototheca* spp. could be nonphotosynthetic mutants of extant *Chlorella* spp. (see Cooke 1968 for references to this mutation theory), there is no evidence that such is the case. Considerable evolutionary diversity would appear to separate the species of these two genera (Nedelcu 2001); with the lone exception that *C. protothecoides* is the postulated phylogenetic ancestor of *P. wickerhamii* (Ueno et al. 2003). From this summary it may be concluded that *Prototheca* spp. are achlorophyllous descendents of *Chlorella* spp., but evolutionary distinctions and further taxonomic hierarchies are speculative.

The discovery of *P. zopfii* during the late nineteenth century notwithstanding, proof of its infectious potential was not obtained until 1952, when it was shown to cause bovine mastitis (Lerche 1952). *P. zopfii* is now known to be the agent of several different animal infections. *Prototheca* spp. stand as the best, if not the only, examples of algae with infectious capabilities in animals and humans. The index human case of dermal protothecosis of the foot (Davies et al. 1964) may also have been caused by *P. zopfii*; however, nearly all subsequent human infections have been caused by *P. wickerhamii*, a microbe belatedly discovered in studies conducted separately by Phaff, Soneda and Wickerham (Tubaki and Soneda 1959). Finally, a few reports incriminate *Chlorella* spp. themselves as infectious agents (see the section on *Chlorella* spp. below).

EPIDEMIOLOGY

Ecology

P. wickerhamii and *P. zopfii* are ubiquitous inhabitants of wastewater (household and municipal sewage), in

which they grow and thrive, ranging in densities up to 10^6 cells/ml (Pore and Boehm 1986). Likewise, they are common in animal waste and agricultural sewage. They also achieve a high population density in some types of tree slime flux (Krüger 1894a, b; Pore 1986). Both species have been isolated in Asia, Europe, North and South America. From these sources they contaminate aquatic systems and food (Pore 1983), and may subsequently be eaten by humans and animals. They pass undigested through the gastrointestinal tract of normal human and monogastric animals tested, with little if any multiplication, and are excreted to resume their saprophytic lifecycle (Pore and Shahan 1988). In a few cases, however, sustained colonization of the gut by *P. wickerhamii* was suspected (see section on Intestinal infection below). Canine protothecal enteritis is a recognized syndrome, and a prelude to systemic involvement (section on Canine infection below). Because of the importance of endemic protothecal mastitis in dairy cattle, a question remaining to be answered is, to what degree are ingested *Prototheca* spp. killed by digestion in ruminants?

Epidemiologic studies by Schuster and Blaschke-Hellmessen (1983), Blaschke-Hellmessen et al. (1987), Pore et al. (1987), and Anderson and Walker (1988) have indicated that *P. zopfii* may be isolated routinely from secreted milk, bulk milk collections, and dairy farm environments. Recent evidence that *P. zopfii* could survive milk pasteurization (Melville et al. 1999) is also of epidemiologic concern.

Relative to the high concentration of *P. wickerhamii* in municipal wastewater and the opportunity for occupational exposure, Clark et al. (1985) did not detect elevated protothecal antibody titers in sewage treatment workers tested. Organically enriched water, in general, not just wastewater, has commonly been incriminated as the source of skin and wound infections, the largest category of human protothecosis cases, but the case reports were anecdotal in nature.

Infections

More than 100 human infections have been documented in the medical literature during the previous 50 years (Krcmery 2000) and, even though many cases may have escaped diagnosis or case reporting, human protothecosis is still considered to be a rare disease. Protothecosis is worldwide in occurrence, but its incidence is low and the disease is not thought to be communicable. Animal infections, on the other hand, may be common, as in bovine protothecal mastitis, but in the past they were mainly undiagnosed by veterinary scientists.

HOST RESPONSES

Clinical presentations of protothecosis

CUTANEOUS

Protothecosis, following naturally occurring skin inoculation, may be the best-documented type of infection by *Prototheca* spp. In several cases, aquariums or wastewater were implicated as the source of the infections, but more frequently no such aqueous source was discovered. The primary cutaneous lesion has not been described, but after several weeks or more, a circumscribed or progressive, indurated, papular rash develops as an early manifestation. Inflammation is usually moderate and the primary symptoms may be pruritus and skin blemishes, although eczematoid reactions may occur. Such primary infections may resolve in some patients, although this has not been documented, and all current reports indicate that the disease is progressive over a period of many years; characteristically exemplified by spreading cutaneous nodules (Figure 1). Well-illustrated recent reports of cutaneous protothecosis include those of Cho et al. 2002, Piyophirapong et al. 2002 and Chao et al. 2002. The infections are not always benign, but may cause burning irritation (Tyring et al. 1989), pseudoepitheliomas or lymphocutaneous spread of granulomatous lesions for up to 18 years (Yip et al. 1976). Some patients are immunocompromised and may develop acanthosis or ulcerative skin lesions (Wolfe et al. 1976; Dagher et al. 1978; Thianprasit et al. 1983; Tejada and Parker 1994; Polk and Sanders 1997; Chao et al. 2002; Piyophirapong et al. 2002).

The index case of protothecosis was a progressive infection of the epidermis and dermis of the foot of an African rice farmer in Sierra Leone (Davies et al. 1964). It started as a small itchy, weeping, raised lesion, which,

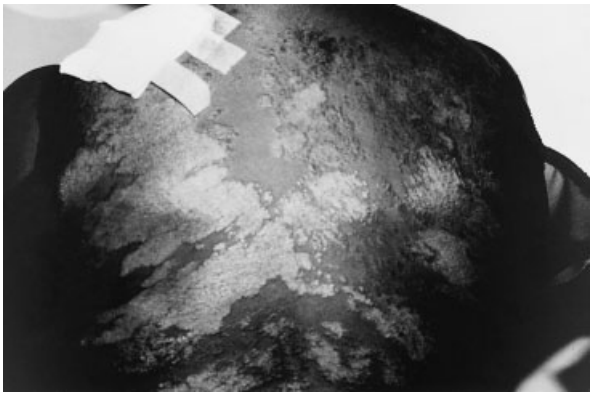

Figure 1 *Progressive cutaneous protothecosis of several years' duration. The spreading, raised plaques lacked pigmentation and were culturally and histopathologically positive for* P. wickerhamii. *The case was reported by Venezio et al. (1982). (Photograph courtesy of John Williams and John Phair)*

5 years later, became a well-demarcated, dry, atrophic, depigmented, papular dermatitis. After 2–3 years, complicated by secondary bacterial infections, the foot had the mossy appearance of elephantiasis. Subsequently, the algal pathogen caused femoral lymphadenitis (Davies and Wilkinson 1967). Although this patient was infected by *P. zopfii* (synonym used was *Prototheca segbwema*), almost all subsequent human infections have been attributed to *P. wickerhamii*. Another well-documented case (Venezio et al. 1982) of several years' duration developed from papular lesions into depigmented scaling plaques covering 50 percent of the skin surface (Figure 1). This case and two others were considered to be the sole reported cases of 'disseminated cutaneous protothecosis' (Thianprasit et al. 1983; Wirth et al. 1999), and all three patients had severe, defective neutrophil functions.

Cutaneous protothecosis may be a superficial form of wound protothecosis, local trauma has been recalled by patients (Chao et al. 2002). From such wounds papules followed by an extensive spreading granulomatous eruption of the skin can develop (Mars et al. 1971; Mayhall et al. 1976; Tang et al. 1995; Kim et al. 1996). *P. wickerhamii* was also the cause of an ulcerating cutaneous papulopustular lesion on the leg of an immunocompromised patient with metastatic adenocarcinoma of the bones. Like the index case, the algae were localized in small foci within the lesions, but the dermatitis was progressive (Klintworth et al. 1968). Raised, plaque-like, verrucose lesions with ulceration have been reported. Forty-five human case reports of all types of protothecosis were reviewed by Nelson et al. (1987) and 34 additional cases of cutaneous infections have been reviewed by Boyd et al. (1995). Resolution of cutaneous infections after antibiotic therapy left considerable residual scarring and atrophy of the skin (Tyring et al. 1989). In three instances patients had simultaneous cutaneous and systemic infections (Cox et al. 1974; Mohabeer et al. 1997; Marr et al. 1998). An infection of the nasopharyngeal mucosa complicated prolonged endotracheal intubation of an insulin-dependent diabetic individual receiving high-dose systemic dexamethasone (Iacoviello et al. 1992). Ulcerations of the hard palate, esophagus, and tongue were inflamed and necrotic, and contained clusters of algal cells that stained lightly with hematoxylin and eosin (H&E), but intensely with periodic acid–Schiff (PAS) and methylene blue.

WOUND INFECTION

Wounds may also be the cause of deeper infections. Accidental dermal and subdermal traumatic inoculation of *P. wickerhamii* during surgery to relieve carpal tunnel syndrome was thought to be the cause of suppurative tenosynovitis (Pegram et al. 1983; Moyer et al. 1990). Again, almost all such human infections were caused by *P. wickerhamii* as annotated by Nelson et al. (1987), along with the source of the infections. Cellulitis, with an aspirate of necrotizing fibrinopurulent exudate containing *P. wickerhamii* occurred in a renal transplant recipient who also received immunosuppressants (Mezger et al. 1981). Subcutaneous wound infections are known to involve tendons and bones in humans (Sirikulchayanonta et al. 1989), dogs (unpublished data) and cats (Coloe 1982). Opportunistic wound infections are probably the second most frequent form of human protothecosis. Three cases of protothecal peritonitis secondary to peritoneal dialysis demonstrate the susceptibility of the compromised abdominal cavity opportunistic infection (O'Connor et al. 1986; Gibb et al. 1991; Sands et al. 1991).

OLECRANON BURSITIS

The relatively high incidence of protothecal olecranon bursitis has led to its recognition as a separate clinical entity. Although the circumstances for traumatic implantation were confirmed in many instances, a number of patients inexplicably reported no prior trauma. The bursa evidently provides a favorable environment for *P. wickerhamii*, and the preexistence of inflammatory conditions and the needle delivery of steroid therapeutics may provide the necessary conditions for infection in some of the cases (Cochran et al. 1986). An underlying immunodeficiency is not a necessary condition for an infection, however (Ahbel et al. 1980). Otherwise normal patients were found to have tender, swollen, olecranon bursas. Aspirated bursal contents were serosanguineous and culturally positive for *P. wickerhamii* (Nosanchuk and Greenberg 1973) or, in a single case, for *P. zopfii* (Naryshkin et al. 1987). Protothecal olecranon bursitis was usually less acute than corresponding bacterial infections. Nelson et al. (1987) have compiled many such protothecal olecranon bursitis cases. Finally, in one instance, olecranon bursitis caused by *P. wickerhamii* was antecedent or coincident with systemic infection (Marr et al. 1998).

INTESTINAL INFECTION

Prototheca portoricensis (another synonym for *P. zopfii*) was proposed as the suspected cause of tropical sprue after its isolation from the feces of two Puerto Rican patients (Ashford et al. 1930). This original observation was never again repeated on sprue patients, despite the efforts of several investigators over the intervening years (Klipstein and Schenk 1975), but the account by Ashford and colleagues does stand as an early attempt to incriminate algae as etiologic agents of infections. In fact, *P. wickerhamii* and *P. zopfii*, originating in the diet, may subsequently be isolated from human and animal feces (Pore and Shahan 1988). *P. wickerhamii* (notably not *P. zopfii*) was isolated on prototheca isolation medium (PIM) from the stools of nine of 500 patients tested (unpublished data). Follow-up was not done for

all nine patients, but for one of the patients, a nutritionally normal, breast-fed, 1-year-old with nonbloody diarrhea of 2 months' duration, the organism was repeatedly recovered on PIM for the final 2 weeks of the diarrhea. At one point in this case fecal dilution plate counting revealed 25 colony-forming units (c.f.u.) per gram of wet stool. A dietary source of the alga was discounted and the microorganism disappeared from the feces near the end of the diarrheal episodes. This patient did not develop any related adverse health problems during 18 subsequent years. All of the other patients also had episodic chronic diarrhea and two of the patients had colony counts of more than 100 c.f.u. per fecal smear on PIM (100 × 15 mm Petri dish). In no case, however, was a causal relationship of the *P. wickerhamii* with the diarrhea established. One infant had pica, but environmental studies on this patient plus four of the others revealed no ingestion source of *P. wickerhamii. P. wickerhamii* was also isolated on PIM from the stools of two Philippine patients, one having acute diarrhea. One culture collection strain of *P. wickerhamii* (CDC B-1280) is labeled 'human intestine.'

An additional case of infant diarrhea, possibly caused by *P. wickerhamii*, has been reported (Casal et al. 1983). In another instance *P. wickerhamii* was repeatedly isolated from the stools of a patient with a well-documented cutaneous protothecosis, but enteritis was not evident or, if evident, not reported (Venezio et al. 1982). Only one case report exists with strong evidence of intestinal protothecosis. This patient with underlying chronic mucocutaneous candidiasis developed a 4-year symptomatology including abdominal pain, diarrhea, and a non-necrotizing granulomatous mass partially obstructing the colon. Histological demonstration of protothecosis was made, but the species was not determined (Raz et al. 1998). Three years later the symptomatology continued and the protothecosis was related to polyps in the colon and ileum. Two patients with systemic protothecosis had a history of antecedent diarrhea (Cox et al. 1974; Heney et al. 1991), and intestinal protothecosis in dogs is not uncommon (see the section on Canine infection below).

SYSTEMIC INFECTION

There are several accounts of human patients with multiorgan protothecosis. A patient having Hodgkin's disease and multiple predisposing factors for secondary infection, and chronic diarrhea of a year's duration, had a mixed *P. wickerhamii*, *Torulopsis glabrata* sepsis, the source of which was probably the long-term Hickman catheter (Heney et al. 1991). Several case reports are available in which the patients had both cutaneous and systemic protothecoses (Cox et al. 1974; Mohabeer et al. 1997; Marr et al. 1998). The first was a rare, chronic, disseminated infection involving the gallbladder, surface of the liver, and the duodenum, in an otherwise normal patient operated upon for symptomatic sclerosing cholangitis (Chan et al. 1990). Two other patients had involvement of the liver, viscera and central nervous system (Matsuda and Matsumota 1992; Takaki et al. 1996). As there was antecedent diarrhea in two cases (Cox et al. 1974; Heney et al. 1991) and a postulated intestinal route of infection or involvement in two others (Chan et al. 1990; Matsuda and Matsumota 1992), these human cases may be compared with the frequently encountered visceral canine protothecosis, which is associated with bloody diarrhea prior to multiorgan dissemination (see the section on Canine infection below). Finally, one case of protothecal endocarditis in a premature infant was reported (Buendia et al. 1998).

IMMUNODEFICIENCY, OPPORTUNISM

In at least half of the published protothecosis cases the patients had a preexisting immune dysfunction or had received immunosuppressive therapy. This was particularly true of the cutaneous and disseminated infections in humans, but has not been as apparent in olecranon bursitis (Woolrich et al. 1994). Corticosteroid treatment appeared to be a significant predisposing factor in several recent cutaneous cases (Chao et al. 2002), and in one otherwise immunocompetent patient, protothecosis developed at the site of cutaneous corticosteroid injection (Kim et al. 1996); another patient who was corticosteroid dependent developed olecranon bursitis with possible subsequent dissemination (Marr et al. 1998). A myasthenia gravis patient receiving corticosteroids developed algemia (prototheca sepsis), but recovered with amphotericin B and gradual elimination of immunosuppressive therapy (Mohabeer et al. 1997). Thirteen cases of protothecosis in cancer patients, several with lymphoid malignancies, have been summarized (Torres et al. 2003). *P. wickerhamii* caused meningitis in one human immunodeficiency virus (HIV)-positive patient (Kaminski et al. 1992) and cutaneous protothecosis in six other AIDS patients (Laeng et al. 1994; Woolrich et al. 1994; Carey et al. 1997; Polk and Sanders 1997; Cunliffe and DiPersio 2000; Piyophirapong et al. 2002). Although other predisposing factors were also present, AIDS was thought to be relevant to the protothecosis. Regarding dogs, immunodeficiency was found to be a significant precondition in several systemic infections (Thomas and Preston 1990). Experimental mouse infections were facilitated by pretreatment with corticosteroids (Pore 1971) as was a naturally occurring disseminated mastitis in a cow (Taniyama et al. 1994).

Animal infections

BOVINE MASTITIS

After its original description and experimental reproduction in Germany (Lerche 1952), protothecal bovine

mastitis has gained worldwide recognition. Caused by *P. zopfii,* protothecal mastitis is mildly inflammatory in comparison to bacterial mastitis; however, it is invasive, reaching the supramammary lymph nodes, chronic, and results in reduced milk production. Twenty-three of 93 dairy cows in one herd were culled (Frank et al. 1969), and 400 cases were reported in New York State (Mayberry 1984). Ten of 192 infected cows in a Danish herd had decreased milk production (Bodenhoff and Madsen 1978), and five of 130 cows were culled for protothecosis, after calving, in the UK (Spalton 1985). A report from Hungary lists 223 cases in 32 herds over 2 years (Janosi et al. 2001b). The only pathogen present in three cases (Dion 1979), and in 10 other cases of mastitis (Chengappa et al. 1984), was *P. zopfii*.

The ubiquity of *P. zopfii* in the dairy farm environment (Schuster and Blaschke-Hellmessen 1983; Blaschke-Hellmessen et al. 1987), and its frequency in milk collections (Pore et al. 1987), provided the foundation for epidemiologic studies (also refer to the section on Ecology below) of bovine mastitis in a herd of 263 cows (Anderson and Walker 1988) and a 52-herd survey (Costa et al. 1998). In the later study, *P. zopfii* was the most common mastitis pathogen recovered (41.2 percent), and this included bacteria. In another large herd, 248 cows were culled for protothecal mastitis. The advanced age of the cows and prior antibiotic treatment for bacterial mastitis were found to be significant risk factors (Tenhagen et al. 1999). Two additional risk factors were found to be high capacity machine milking and poor herd management (Corbellini et al. 2001b; Janosi et al. 2001a). A review of protothecal bovine mastitis included a more comprehensive discussion of pathogenesis and possible control measures (Pier et al. 2000).

Despite the postulated decrease in milk production, protothecal mastitis is an underreported dairy cow disease. Factors responsible include:

- the reluctance of dairy farmers to admit to mastitis in their herds
- insufficient information about protothecal mastitis etiology
- the relatively low white blood cell counts in the milk
- the lack of a treatment regimen
- the ease of culling and its economic advantages.

Both mastitic and non-mastitic dairy cows have been found to have elevated levels of anti-*P. zopfii* antibodies (Jensen et al. 1998), and a recently developed enzyme-linked immunosorbent assay (ELISA) test based on elevated serum IgA and IgG, and whey IgA against *P. zopfii* (Roesler and Hensel 2003) presents the opportunity for screening infected herds and advancing epidemiologic research.

CANINE INFECTION

After chronic hemorrhagic diarrhea in a domestic dog that was attributed to *Prototheca* spp., necropsy revealed small, white, granulomatous nodules containing numerous cells of *Prototheca* spp. in the intestinal mucosa and wall, peritoneal cavity, myocardium, kidneys, liver, and spleen (Buyukmihci et al. 1975). Notable in this case was necrotizing granulomatous chorioretinitis leading to blindness. Similarly, Cook et al. (1984) described a dog presenting with blindness and deafness, that had had a previous bloody diarrhea and ultimately developed multiorgan system involvement. In this case, *P. zopfii* was identified by fluorescent antibody stains as it was in a similar third case (Gaunt et al. 1984). In a fourth example, blindness caused by microabscesses containing *P. wickerhamii* under the detached retina was preceded by an enterocolitis (Font and Hook 1984). It appears, based on a review of 12 such cases, that hemorrhagic diarrhea and disseminated protothecosis is a distinctive syndrome that can be caused by either *P. wickerhamii* or *P. zopfii* after protothecal colitis in dogs (Migaki et al. 1982). Similar cases were reported and the syndrome reviewed (Rakich and Latimer 1984; Thomas and Preston 1990; Rallis et al. 2002). Attention was drawn to the fact that the syndrome is most common in the Collie breed and the similar features of immunodeficiencies in both canine and human protothecoses. However, not all dogs with disseminated protothecosis had documented antecedent intestinal infections (Tyler et al. 1980), so the syndrome and its epidemiology need further elucidation. Myocardial infection may also be a significant manifestation of systemic canine protothecosis (Moore et al. 1985). To summarize, early recognition of canine protothecosis syndrome should include manifestations of chronic diarrhea and/or acute blindness, this indicating the most opportune time for therapeutic intervention (Hollingsworth 2000).

OTHER ANIMAL INFECTIONS

Kaplan (1978) compiled information on 42 case reports of protothecosis in animals and 18 in humans. He included several cases attributable to *Chlorella* spp. as well (Kaplan et al. 1993). Disseminated protothecosis in cattle has also been described (Migaki et al. 1969), and it may be acute, causing massive necrotic mastitis, kidney infarction, pulmonary artery thrombosis and colitis (Taniyama et al. 1994). In this last instance a cow was simultaneously infected with *P. zopfii, Aspergillus* sp. and a zygomycete (Taniyama et al. 1994). Cutaneous protothecosis caused by *P. wickerhamii* in two cats has some of the features of human infections (Dillberger et al. 1988), and a spreading mucocutaneous infection of the nares of a dog has been well documented (Sudman et al. 1973); otherwise, descriptions of cutaneous infections in animals have been rare. One cutaneous dog infection was thought to be the primary manifestation of a case of systemic protothecosis (Ginel et al. 1997).

Experimental infection

P. zopfii was pathogenic for mice after intraperitoneal inoculation (Schiefer and Gedek 1968). Weakly inflammatory, but chronic, infections of the kidney capsule and kidney tubules were the prominent manifestations (Pore 1971), and hydrocortisone treatment enhanced the experimental infection of mice by *P. wickerhamii* (Pore 1971). de Camargo et al. (1980) were less successful and only obtained intratesticular infections in laboratory animals, but Horiuchi and Masuzawa (1995) successfully demonstrated a mouse model for cutaneous protothecosis. In this experimental model *P. wickerhamii* caused epithelioid cell granulomas in BALB/c mice while ICR mice were less vulnerable. Experimental mastitis in cows, after introduction of *P. zopfii* through the teat canal, led to well-documented progressive pyogranulomatous infections (Lerche 1952; Frank et al. 1969; McDonald et al. 1984). The experimental infections mimicked natural infections and *P. zopfii* was subsequently isolated from secreted milk. Schiefer and Gedek (1968) produced mastitis with *Prototheca moriformis* – another potential cause of bovine mastitis (Pore et al. 1987). *P. zopfii* was lethal for immunosuppressed mice in one study (Jensen and Aalbaek 1994). Finally, cells of *Chlorella* spp. persisted in the peritoneal cavity of rats with minimal pathogenesis (Rogers et al. 1980), but even *Prototheca* spp. were not very aggressive pathogens in normal laboratory rodent models of infection.

Immunology

About half the patients with protothecosis have immunodeficiencies prior to or coincident with their protothecosis. These immunodeficiencies differ, but commonly fall within the same category as those for patients with increased susceptiblity to opportunistic fungal infections. One opportunistically predisposed patient was simultaneously infected with *P. wickerhamii* and the fungus *Exophialia jeanselmei* (*Phialophora gougerotti*) (McAnally and Parry 1985), while another patient had *P. wickerhamii* and *T. glabrata* (Heney et al. 1991). A typical example of predisposition was a patient receiving long-term prednisolone for systemic lupus erythematosus who developed cutaneous protothecosis after an injury. The combination of oral prednisolone and cyclophosphamide in a patient with systemic lupus erythematosus was a contributing immunosuppressive factor for another patient with cutaneous protothecosis (Thianprasit et al. 1983). A significant number of protothecosis patients received local corticosteroid injections in soft tissues or the olecranon bursa (Nelson et al. 1987) or in skin lesions (example of two cases; Walsh et al. 1998). Patients with malignancies and other immunosuppressive factors above have been reviewed (Torres et al. 2003). Corticosteroids may predispose patients to opportunistic protothecosis and mycoses by suppressing T-cell-mediated immunity, as do cytotoxic agents and other immunosuppressants. Cutaneous protothecosis has been described more than once in patients receiving combination immunosuppressive therapy to combat graft rejection (Wolfe et al. 1976), as has chemotherapy-induced neutropenia in a patient with acute myelocytic leukemia (Wirth et al. 1999). Corticosteroids, antilymphocyte globulin, and cytotoxic drugs predispose patients to opportunistic bacterial and fungal infections as well as cutaneous abscesses caused by *P. wickerhamii*. There is evidence that *P. wickerhamii* itself may be immunoinhibitory (Perez and Ginel 1997).

Intracellular killing of *P. wickerhamii* by human polymorphonuclear neutrophils (PMNs) in vitro was enhanced in the presence of humoral factors that stimulated oxidative metabolism and degranulation (Phair et al. 1981). Subsequent research linked this finding to a case of protothecosis in a patient who had a specific defect in PMN killing of *P. wickerhamii* (Venezio et al. 1982), but nonspecific acquired immunity in this case was normal. Likewise, a severe oxidative burst defect in peripheral blood neutrophils was found to be contributory to protothecosis in an AIDS patient (Carey et al. 1997). Similarly, a Collie dog with disseminated protothecosis had a serum-mediated defect in PMN chemotaxis (Rakich and Latimer 1984). Natural killer cell activity was suppressed in one patient with cutaneous protothecosis (Tyring et al. 1989). Finally, one patient with disseminated protothecosis, who had developed a high specific IgG titer to *P. wickerhamii*, possessed a normal cell-mediated immune system (Chan et al. 1990), but another with a high serum titre had a blast transformation deficiency specific for the microorganism (Cox et al. 1974). These patient studies indicate that protothecosis, like several of the mycoses, may not be ameliorated by the humoral immune system and indicate that nonspecific leukocyte defects are paramount susceptibility factors.

Treatment

SURGERY

Surgical excision has been a successful means of treating localized cutaneous protothecosis (Thianprasit et al. 1983; Cunliffe and DiPersio 2000), wound protothecosis (Sirikulchayanonta et al. 1989; Tejada and Parker 1994) and protothecal and olecranon bursitis (Ahbel et al. 1980; Vernon and Goldman 1983; Naryshkin et al. 1987), often combined with an antibiotic. Wound infections have responded to débridement plus amphotericin B (Moyer et al. 1990; Walsh et al. 1998), and intrabursal amphotericin B alone was successful (Cochran et al. 1986). Removal of a right atrial mass followed by amphotericin B resolved a case of protothecal endocarditis in a premature infant (Buendia et al. 1998).

AMPHOTERICIN B

Amphotericin B alone has been used successfully to treat cutaneous infections (Mayhall et al. 1976; Thianprasit et al. 1983; Carey et al. 1997; Chao et al. 2002), a mucosal infection of the pharynx (Iacoviello et al. 1992) and a case of algemia, together with the removal of a Hickman catheter (Heney et al. 1991). Amphotericin B, followed by ketoconazole therapy, was successful in a case of systemic human protothecosis (Chan et al. 1990), but failed in a similar case in a dog (Moore et al. 1985). Amphotericin B alone was not efficacious in a case of cutaneous protothecosis (Yip et al. 1976); but amphotericin B has also led to cures (Chao et al. 2002). Combined with transfer factor, amphotericin B was effective in a case of disseminated human protothecosis (Cox et al. 1974). Intestinal protothecosis did not respond to amphotericin B alone (Raz et al. 1998). Tetracycline has had postulated synergistic activity with amphotericin B (Venezio et al. 1982; Tyring et al. 1989; Sands et al. 1991). Aminoglycosides and tetracycline were good inhibitors in susceptibility tests (Shahan and Pore 1991), but they lacked efficacy in a mucocutaneous dog infection (Sudman et al. 1973). Although tetracycline after surgery (Sirikulchayanonta et al. 1989) and oral tetracycline plus topical amphotericin B (Tyring et al. 1989) are reported to be successful therapeutic agents, tetracycline alone has also failed as a treatment for protothecosis (Wolfe et al. 1976). So, in light of increasing success with azoles (see the next section), tetracycline therapy is not promising. In patients with specific neutrophil killing defects, it may be advantageous to use a cidal agent such as amphotericin B (Carey et al. 1997). The same may be true for patients developing chemotherapy-induced neutropenia (Torres et al. 2003), along with amelioration of the neutropenia (Wirth et al. 1999).

AZOLES

Recent reports of successful therapy of cutaneous protothecosis with oral azoles are promising. A case of cutaneous eczematous dermatitis of the eyelid was successfully treated with oral ketoconazole over a 4-month period (Kuo et al. 1987), as was a post-surgical wrist infection (Pegram et al. 1983), but failures of ketoconazole treatment have also been reported (McAnally and Parry 1985; Walsh et al. 1998). Oral fluconazole has proven successful (Follador et al. 2001) as has 200 mg/day oral itraconazole (Boyd et al. 1995; Tang et al. 1995; Okuyama et al. 2001; Cho et al. 2002). Instances of failure of itraconazole (Carey et al. 1997) and fluconazole (Walsh et al. 1998) have also been reported. In one instance, a cutaneous infection that did not respond to itraconazole was successfully resolved with fluconazole (Kim et al. 1996), and another with amphotericin B (Carey et al. 1997). Itraconazole alone was not satisfactory for intestinal protothecosis, but in combination with interferon-gamma (IFN-γ), the patient improved (Raz et al. 1998). Favorable treatment results were achieved with fluconazole for peritonitis (Gibb et al. 1991).

In a report of five cutaneous cases compromised by steroid treatment, successful resolution of each separate case occurred by using ketoconazole, fluconazole, or itraconazole (Chao et al. 2002). In the other two cases, intravenous amphotericin B or intralesional amphotericin B resulted in cures. In the case of AIDS-related cutaneous infections, oral ketoconazole was not successful, but 2 g intravenous amphotericin B for 10 weeks resulted in resolution that was maintained for 3 years (Piyophirapong et al. 2002).

RESISTANCE

Currently, the management of disseminated protothecosis with conventional antibiotics remains an open question, as exemplified by the patient who received three different azoles and amphotericin B, but remained infected (Takaki et al. 1996). Even though azoles and polyenes may be efficacious in humans, azoles give unreliable susceptibility data, and the development of resistance has been noted (Takaki et al. 1996). *P. wickerhamii* is uniformly sensitive to amphotericin B in in vitro susceptibility tests (Segal et al. 1976), but an exception has been noted (Takaki et al. 1996). Notably, both *P. wickerhamii* and *P. zopfii* are resistant to 5-fluorocytosine (Pore 1973). Likewise, both species may be resistant to fluconazole and itraconazole, at least according to the E-test (Blaschke-Hellmessen 1996; Linares et al. 1998), but this finding is in need of confirmation in light of the successful therapies reported above. Similarly to the situation with yeasts, successful therapy of protothecosis with azoles does not necessarily correspond to conventional minimum inhibitory concentration (MIC) susceptibility testing results, which can be equivocal, yet azoles are often efficacious therapies. Finally, it should be kept in mind that all infections responding to antibiotics were caused by *P. wickerhamii*.

LABORATORY DIAGNOSIS

Isolation and culture

FROM BLOOD, CSF, AND TISSUE

P. wicherhamii and *P. zopfii* grow aerobically on conventional Sabouraud's and blood agar media after 24–48 hours at room temperature up to 35°C. The small colonies are grossly indistinguishable from yeast colonies. As these two pathogenic *Prototheca* spp. may be sparse in clinical specimens, a large, fresh, preferably unrefrigerated specimen should be processed for culture. Notably, *Prototheca* spp. similar to *Cryptococcus* spp., are uniformly inhibited in vitro by common culture medium additives such as cycloheximide, tetracycline

(Mezger et al. 1981), and aminoglycosides (Shahan and Pore 1991).

FROM STOOLS

As *Prototheca* spp. may be overgrown by faster growing microorganisms and hence usually unrecoverable from contaminated specimens, PIM (Table 1), which contains phthalate to suppress bacteria and 5-fluorocytosine to suppress yeasts, was found to be a good selective isolation medium for *Prototheca* spp. from contaminated sources (Pore 1973). A subsequent modification included the addition of rose Bengal (4,5,6,7-tetrachloro-2′,4′,5′,7′-tetraiodofluorescein sodium salt) for further suppression of fungal and bacterial growth (Pore 1983). Specimens may be smeared or streaked with a swab and, after 48–72 hours, yeast-like colonies will become visible with the aid of a low-power stereomicroscope. Not all yeast species are suppressed by PIM, so suspicious colonies should eventually be examined at magnifications of 400 × with a compound microscope.

Microbiology

MORPHOLOGY

Colonies have a yeast-like appearance, but microscopically, budding is absent. Reproduction of *Prototheca* spp. is via the formation of a variable number of sporangiospores (commonly two to eight) within a sporangium (Figure 2). The sporangiospores are released through a characteristic split in the sporangial wall and usually disperse (Figure 3). The reproductive morphology is identical to that of most *Chlorella* spp. and is the basis for a postulated phylogenetic relationship to the algae; however, *Prototheca* spp. lack plastids

Table 1 *Prototheca isolation medium (PIM)*

Ingredients	Amount
Distilled water	1 l
Potassium hydrogen phthalate[a]	10 g
Sodium hydroxide	0.9 g
Magnesium sulfate	0.1 g
Potassium phosphate, monobasic	0.2 g
Ammonium chloride	0.3 g
Thiamine	0.001 g
Rose Bengal	0.0025 g
Glucose	10 g
Purified agar	15 g

a) Adjust to pH 5.1 ± 0.1 with NaOH before sterilization; autoclave for 15 min; after sterilization add 5-fluorocytosine (0.25 g) (Pore 1973). The potassium hydrogen phthalate is the unmetabolizable buffer; it also serves to enhance growth in an unknown way and suppresses growth of most bacteria and fungi in contaminated specimens. A modification of this medium (Pore et al. 1987) is an enrichment medium for the recovery of *P. zopfii* from milk and the environment. *C. protothecoides,* but not other species of *Chlorella*, also grows on PIM. Another modification (Pore 1985, 1998) is the filter-sterilized, PIM, minimum essential medium for assimilation and identification to species.
